

Two-dimensional correlation spectroscopy in solids

Jeremy Titman,
School of Chemistry, University of Nottingham

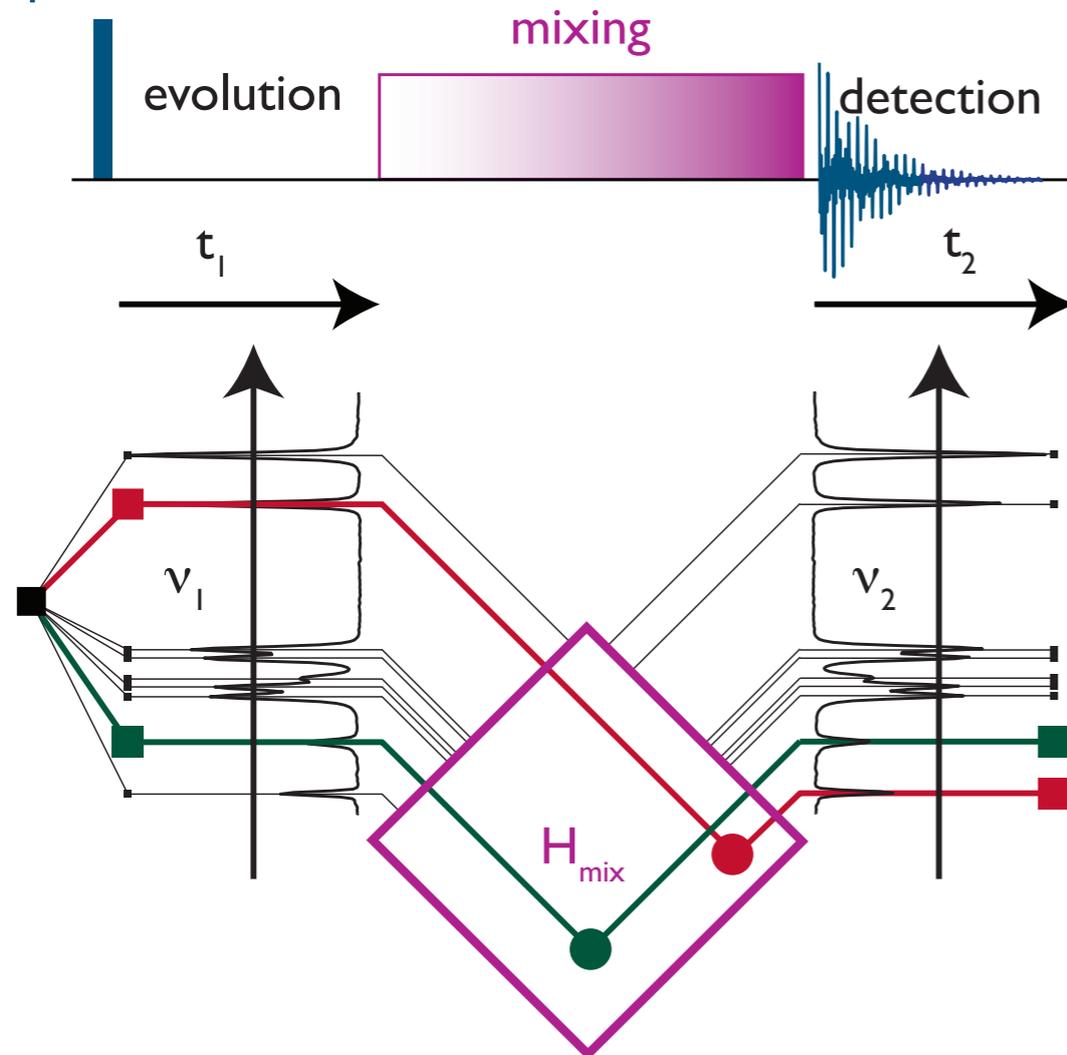

Two-dimensional correlation spectroscopy

A two-dimensional correlation experiment consists of four time periods: Preparation, evolution, mixing and detection.

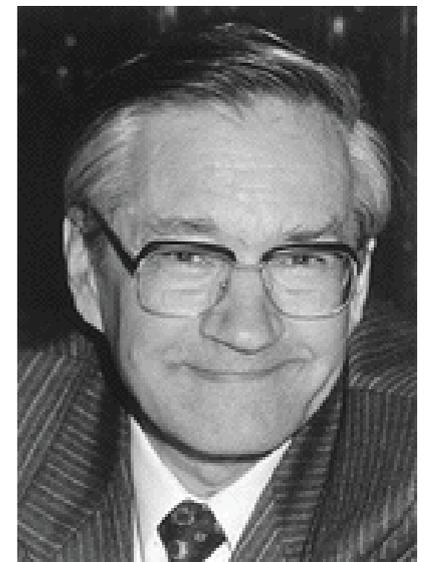

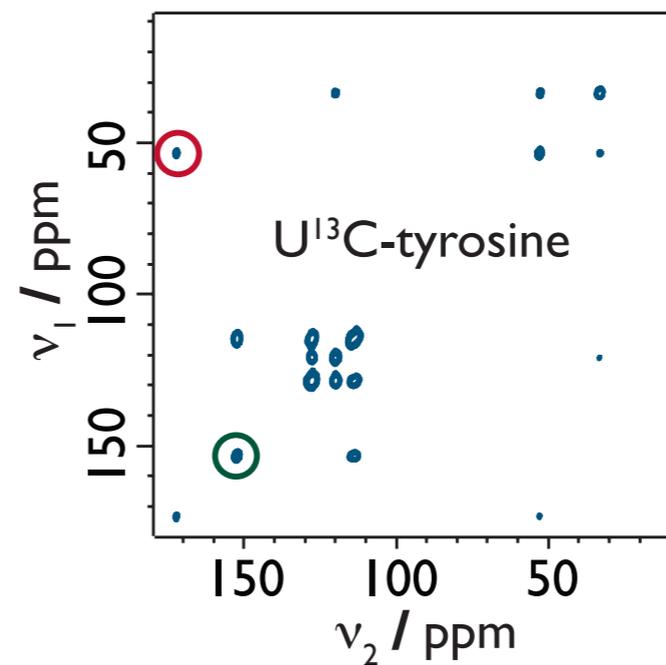

- ★ Magnetization is transferred between the spins during the mixing period.
- ★ The signal $S(t_1, t_2)$ is a function of both the evolution and the detection time.

A two-dimensional Fourier transform generates a two-dimensional spectrum $S(\nu_1, \nu_2)$.

Richard Ernst

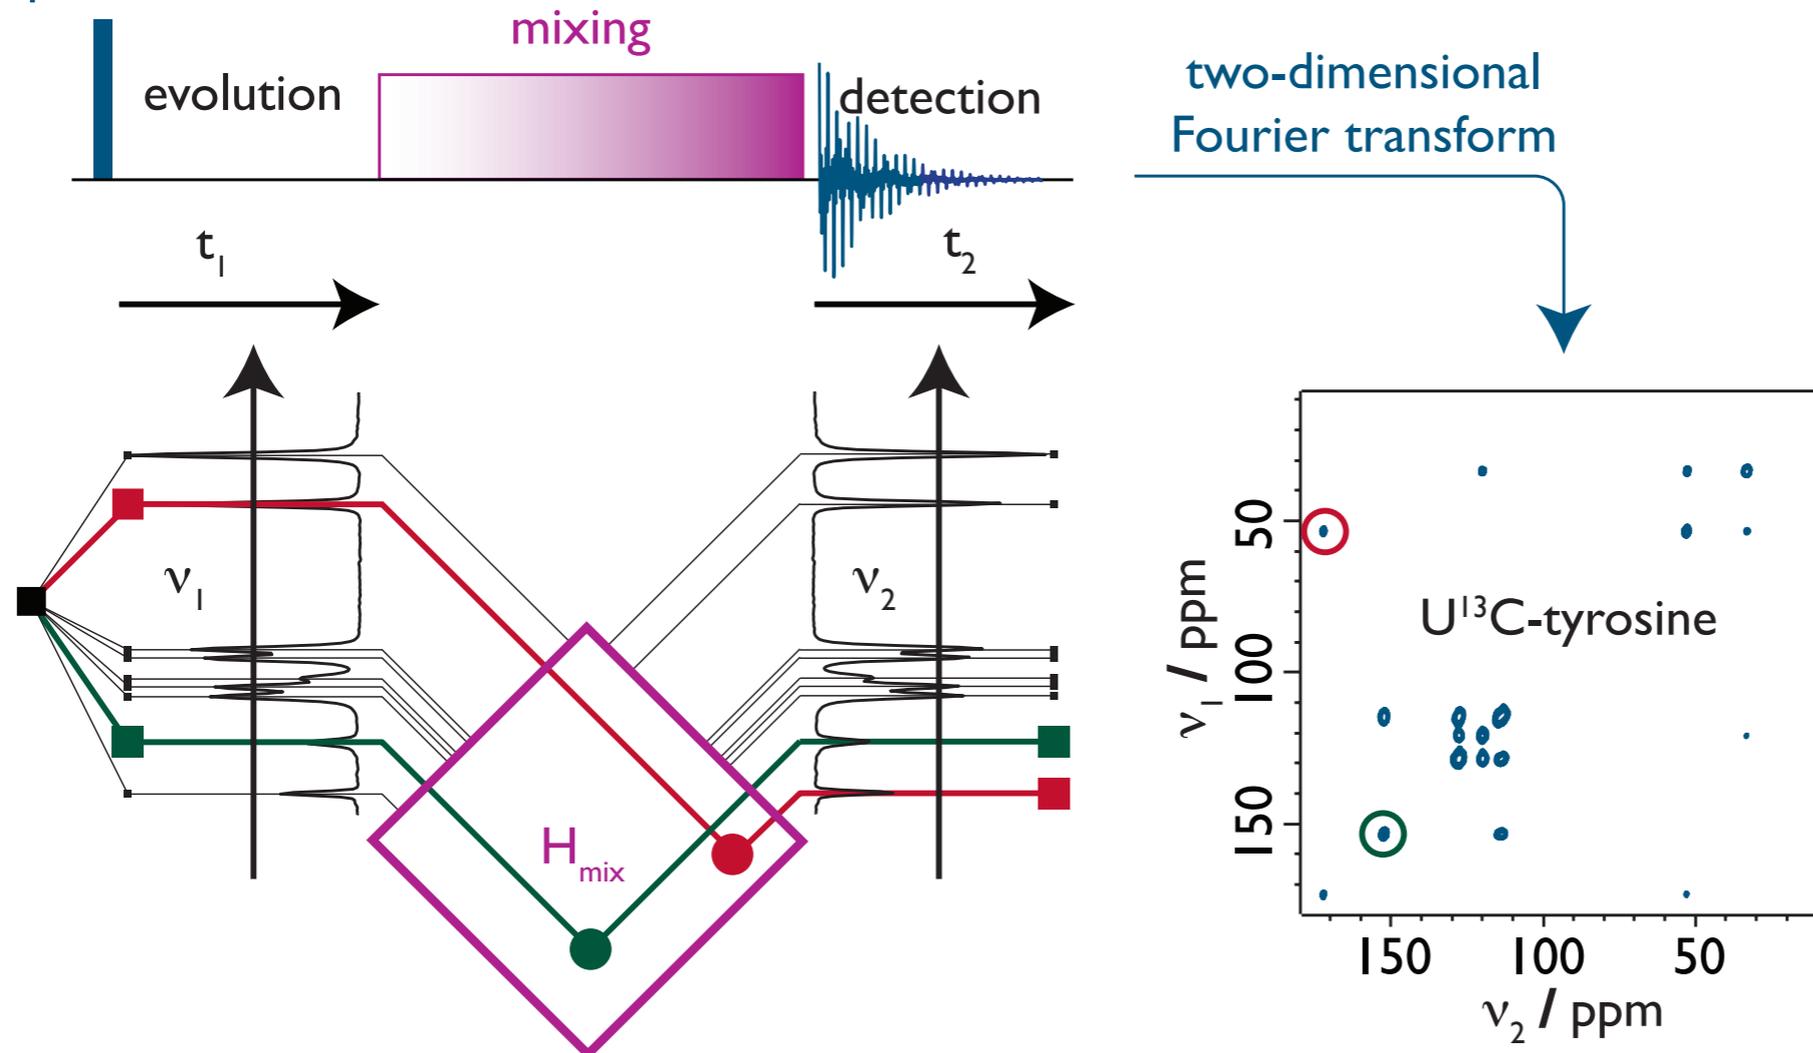

Cross and diagonal peaks

Two types of peaks can be observed in correlation spectra:

- ★ **Diagonal peaks** for which $\nu_1 = \nu_2$. This indicates that the mixing process did not transfer magnetization between spins.
- ★ **Cross peaks** for which $\nu_1 \neq \nu_2$. This indicates that magnetization has been transferred from a spin precessing at a frequency ν_1 in the first dimension to a spin precessing at ν_2 in the second.

The nature of the mixing process dictates the information content of the two-dimensional spectrum.

preparation

Types of correlation

Dipolar correlations

- ★ Cross peaks link pairs of spins which are dipolar coupled to one another. These are close together in space, but not necessarily bonded.
- ★ Because the magnitude of the dipolar interaction depends on the internuclear distance, these experiments can be used to measure atomic separations in molecules.
- ★ The dipolar coupling is motionally averaged in solution, so cross relaxation is used. In a solid the magnetization transfer can be achieved coherently.

Scalar correlations

- ★ Cross peaks link pairs of spins with a mutual J coupling. Because this interaction requires a chemical bond between the coupled spins, cross peaks link sites in the molecule which are bonded together.
- ★ This is useful for assigning lines in a complicated spectrum to sites in the molecule and for establishing molecular structure.

Philosophy

“Solution-like” approach:

Rapid MAS, Efficient Decoupling

$$H = H_{\text{iso}}$$

No orientational information; recoupling

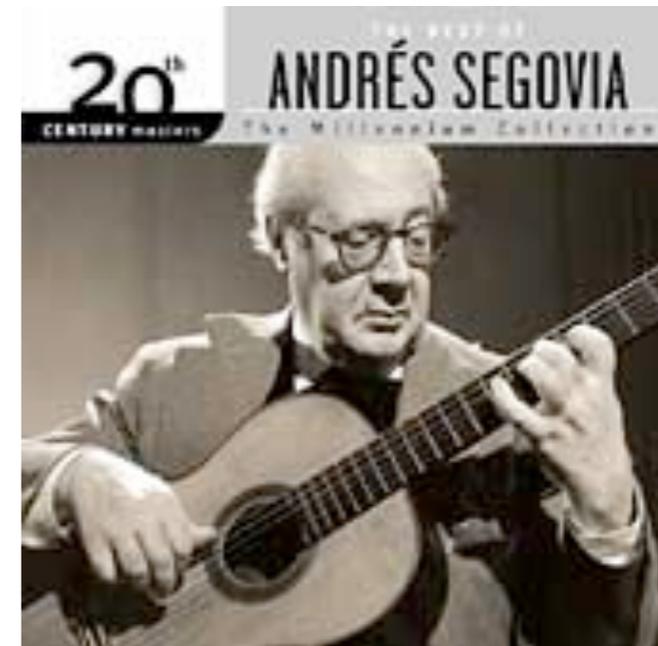

“Classical solids” approach:

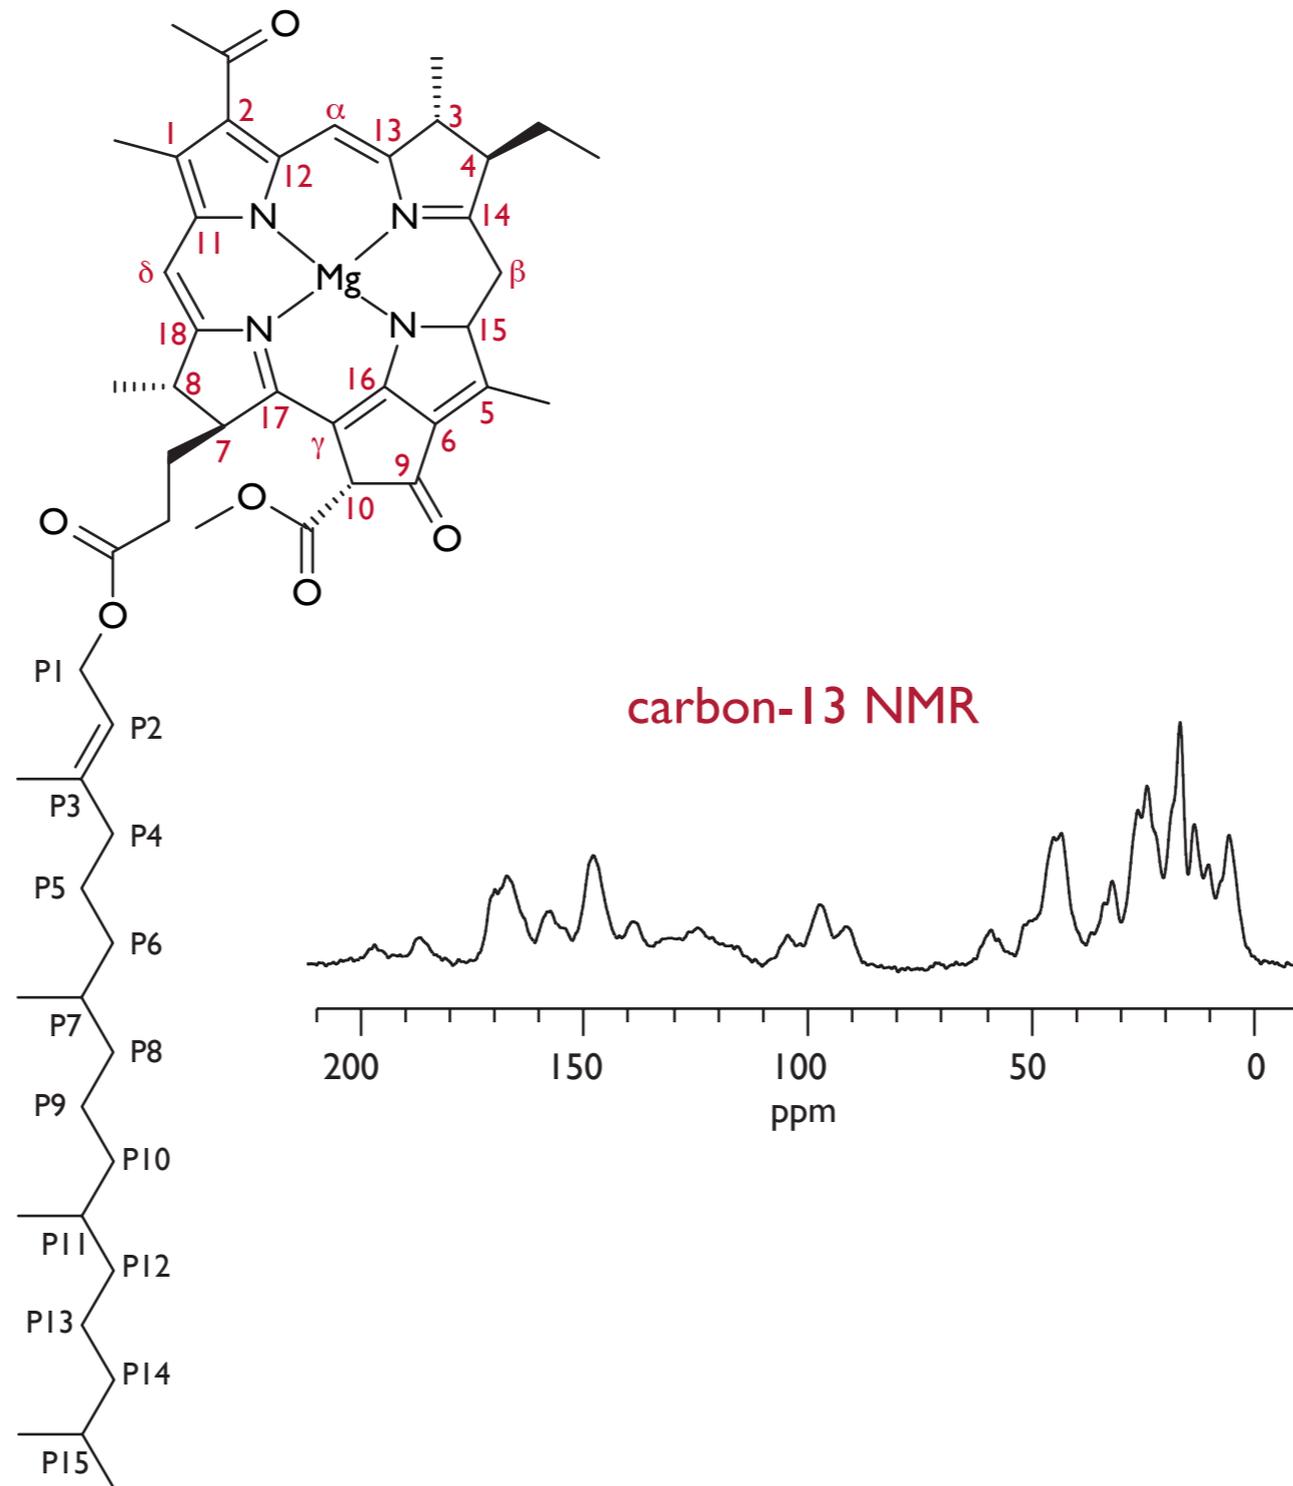

Slow (or no) MAS

$$H = ?$$

Retain orientational information

Carbon-13 assignment for bacteriochlorophyll a

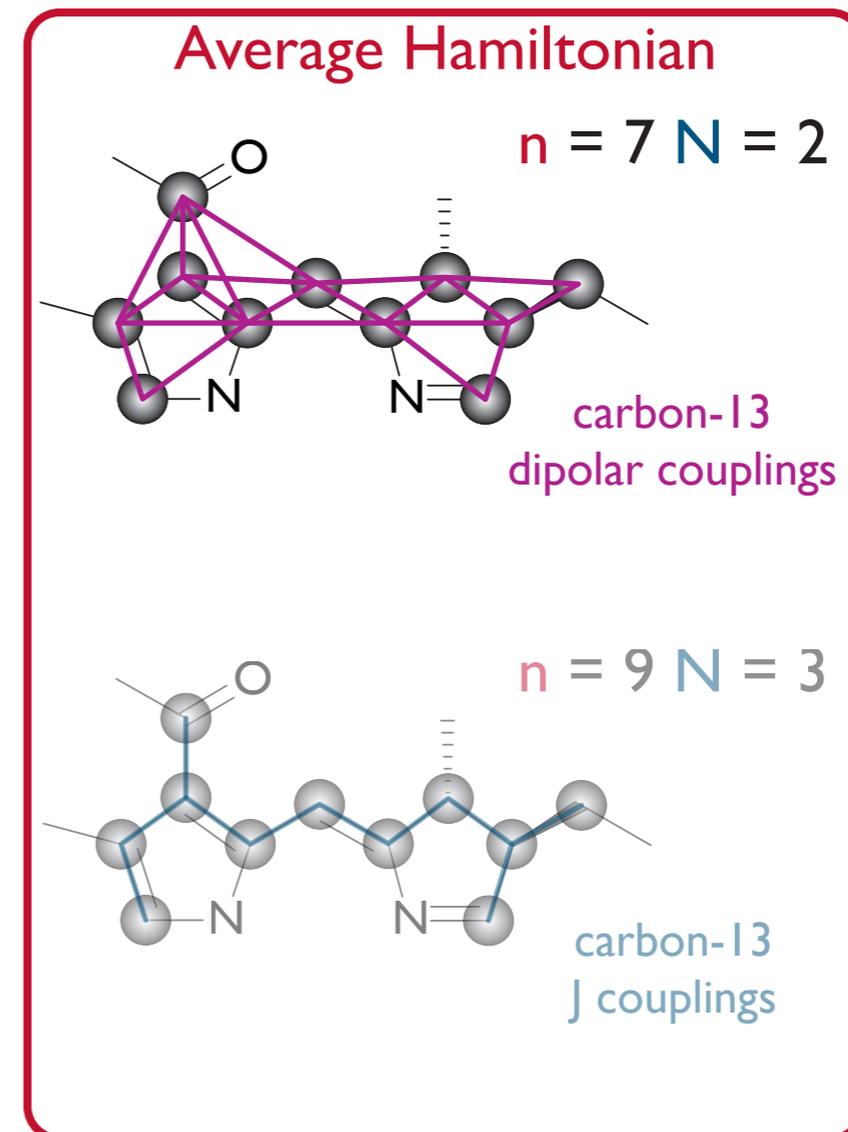

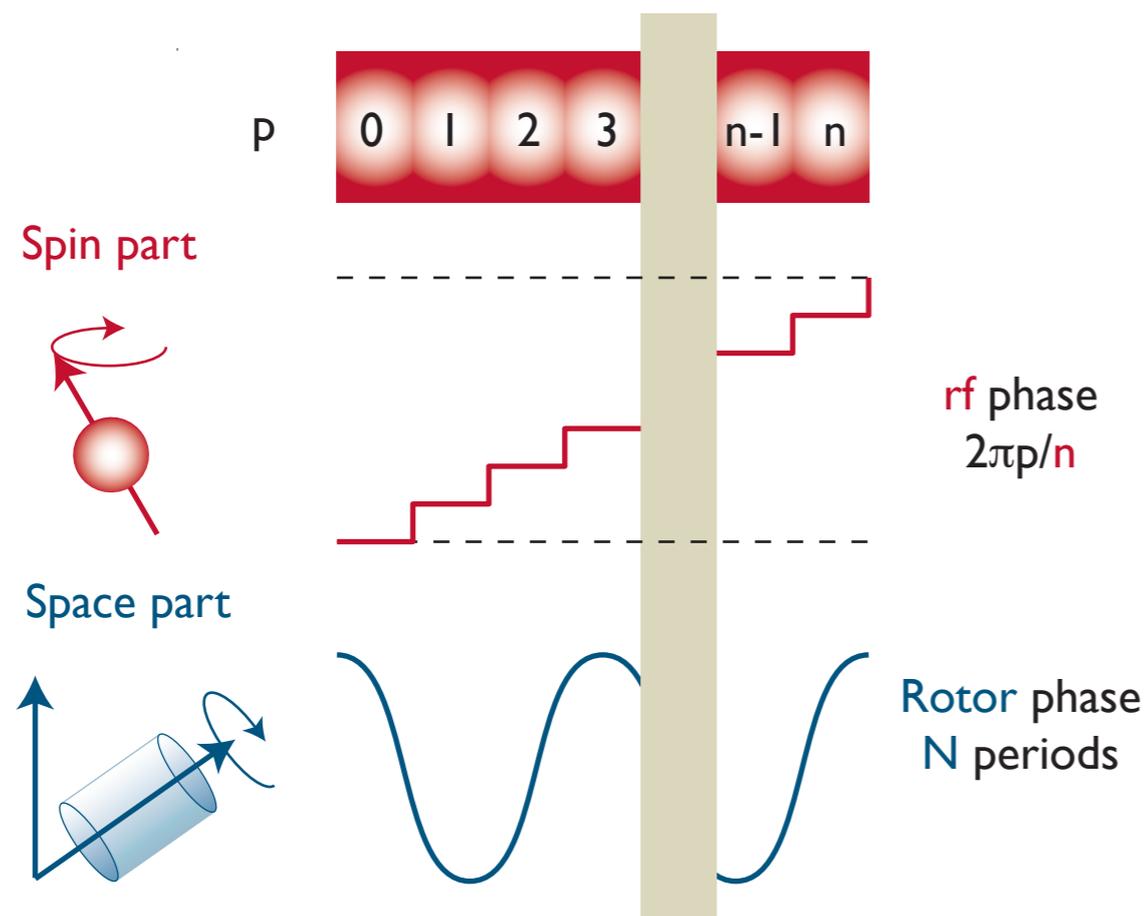

What is the assignment of the sites to the resonances?

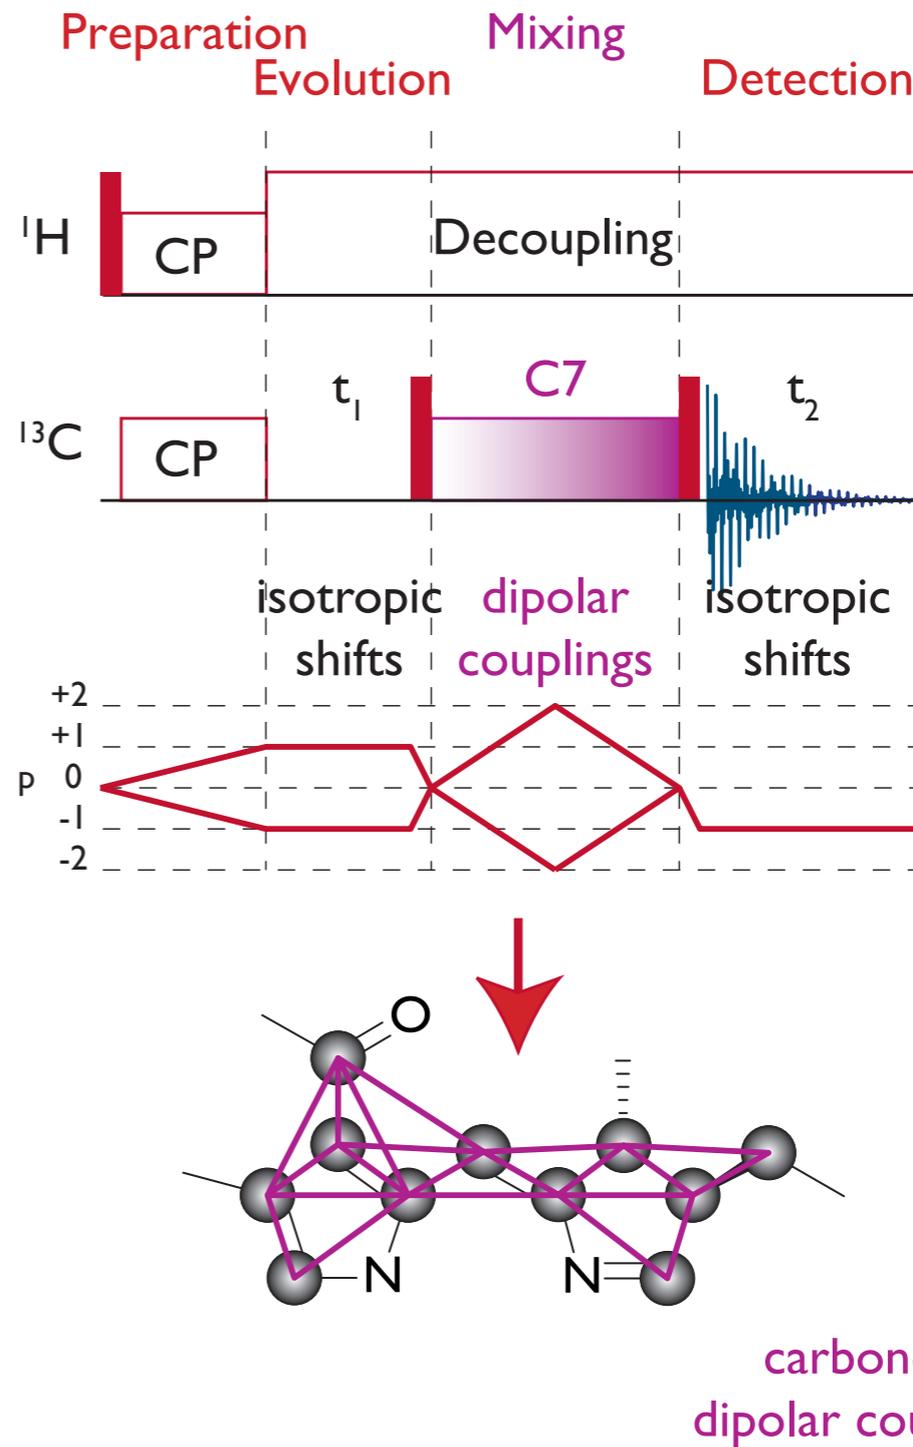

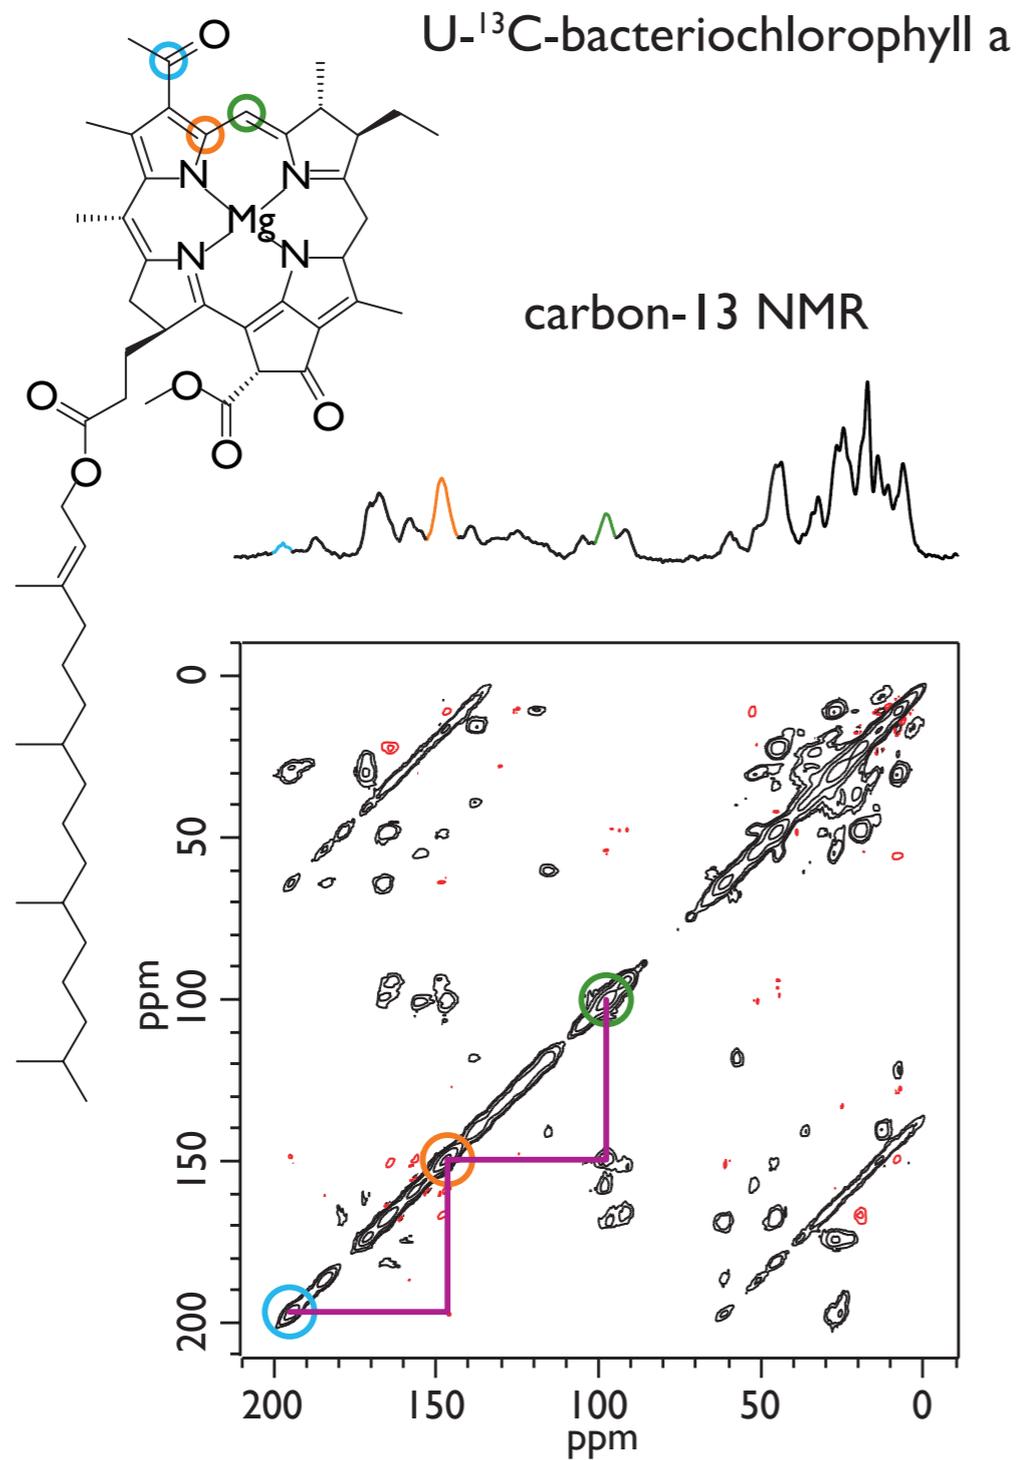

Dipolar recoupling

The double-quantum dipolar Hamiltonian is recoupled in the mixing period, causing magnetization transfer between dipolar-coupled spins.

$$H_{\text{mix}} \propto (I_1^+ I_2^+ + I_1^- I_2^-)$$

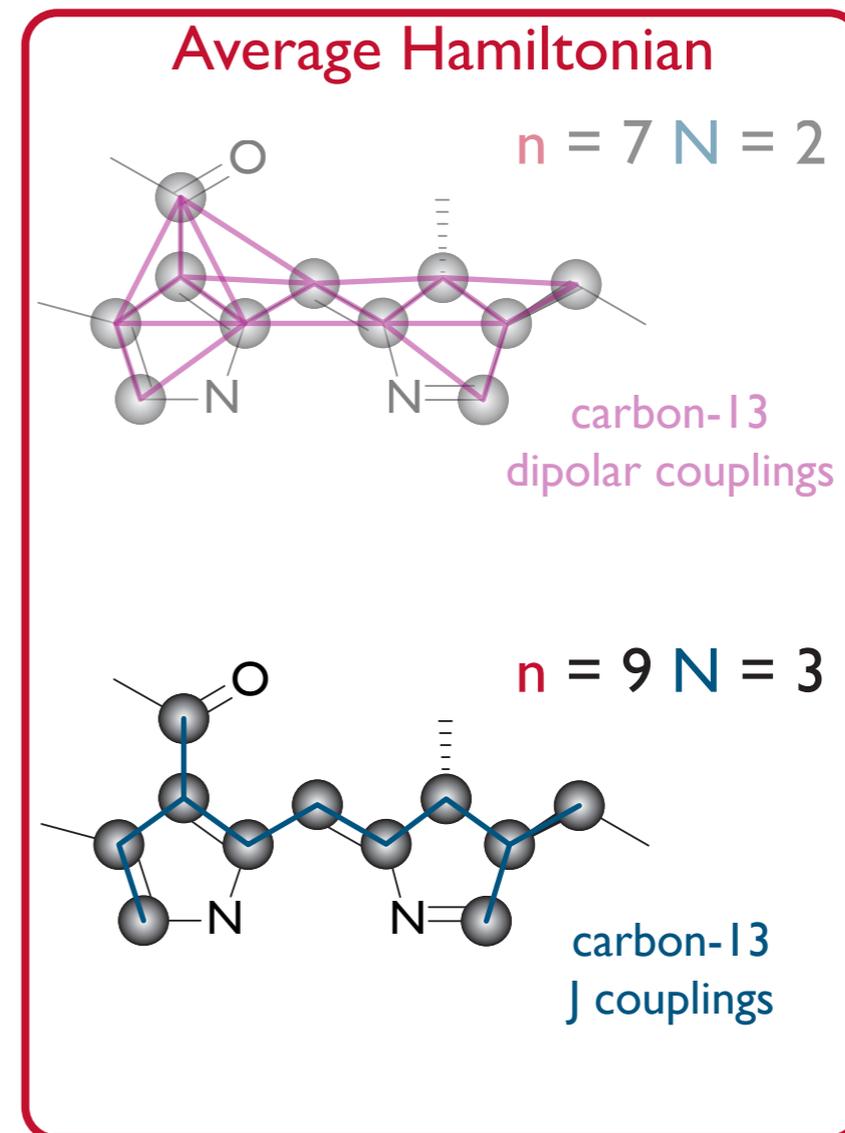

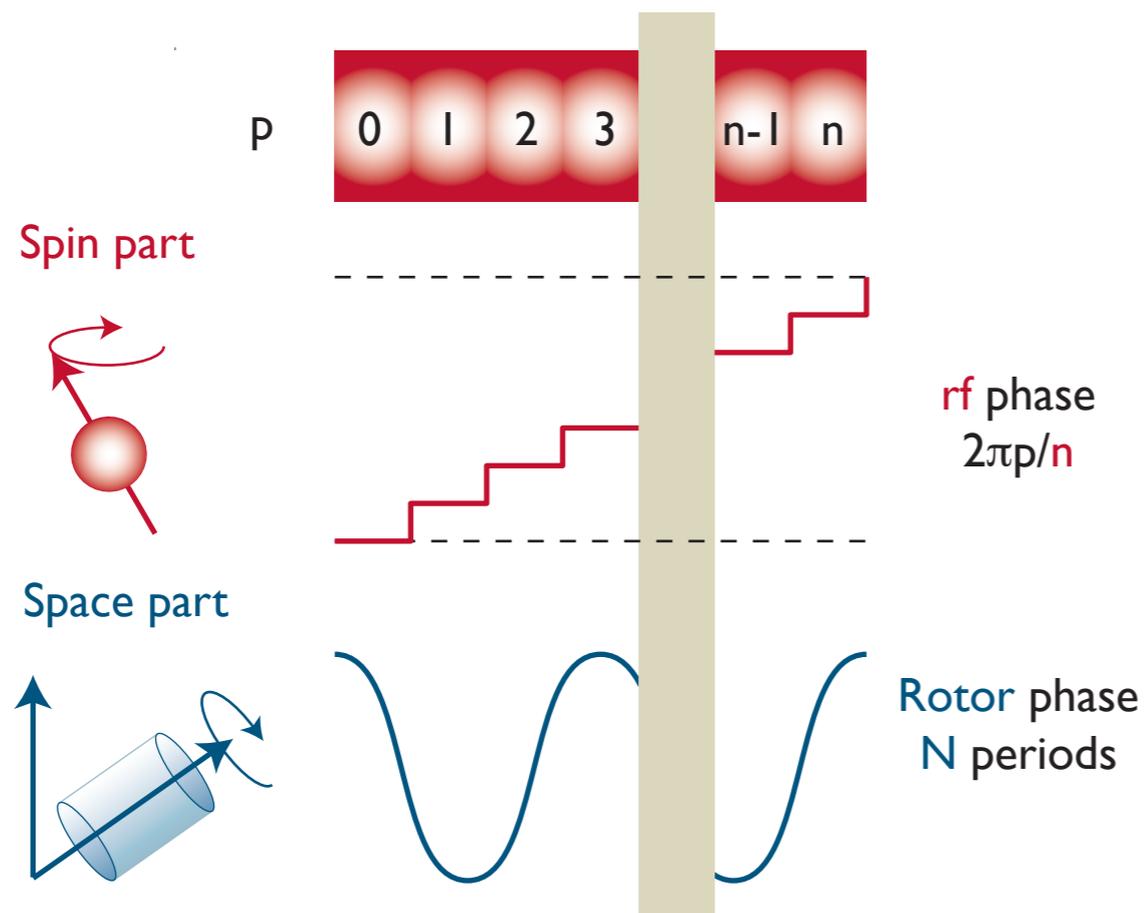

Dipolar correlation

Pulse sequence symmetry

Changing the pulse sequence symmetry reintroduces the isotropic mixing scalar Hamiltonian during the mixing time, causing magnetization transfer between scalar-coupled spins.

$$H_{\text{mix}} = 2\pi J \mathbf{I}_2 \cdot \mathbf{I}_2$$

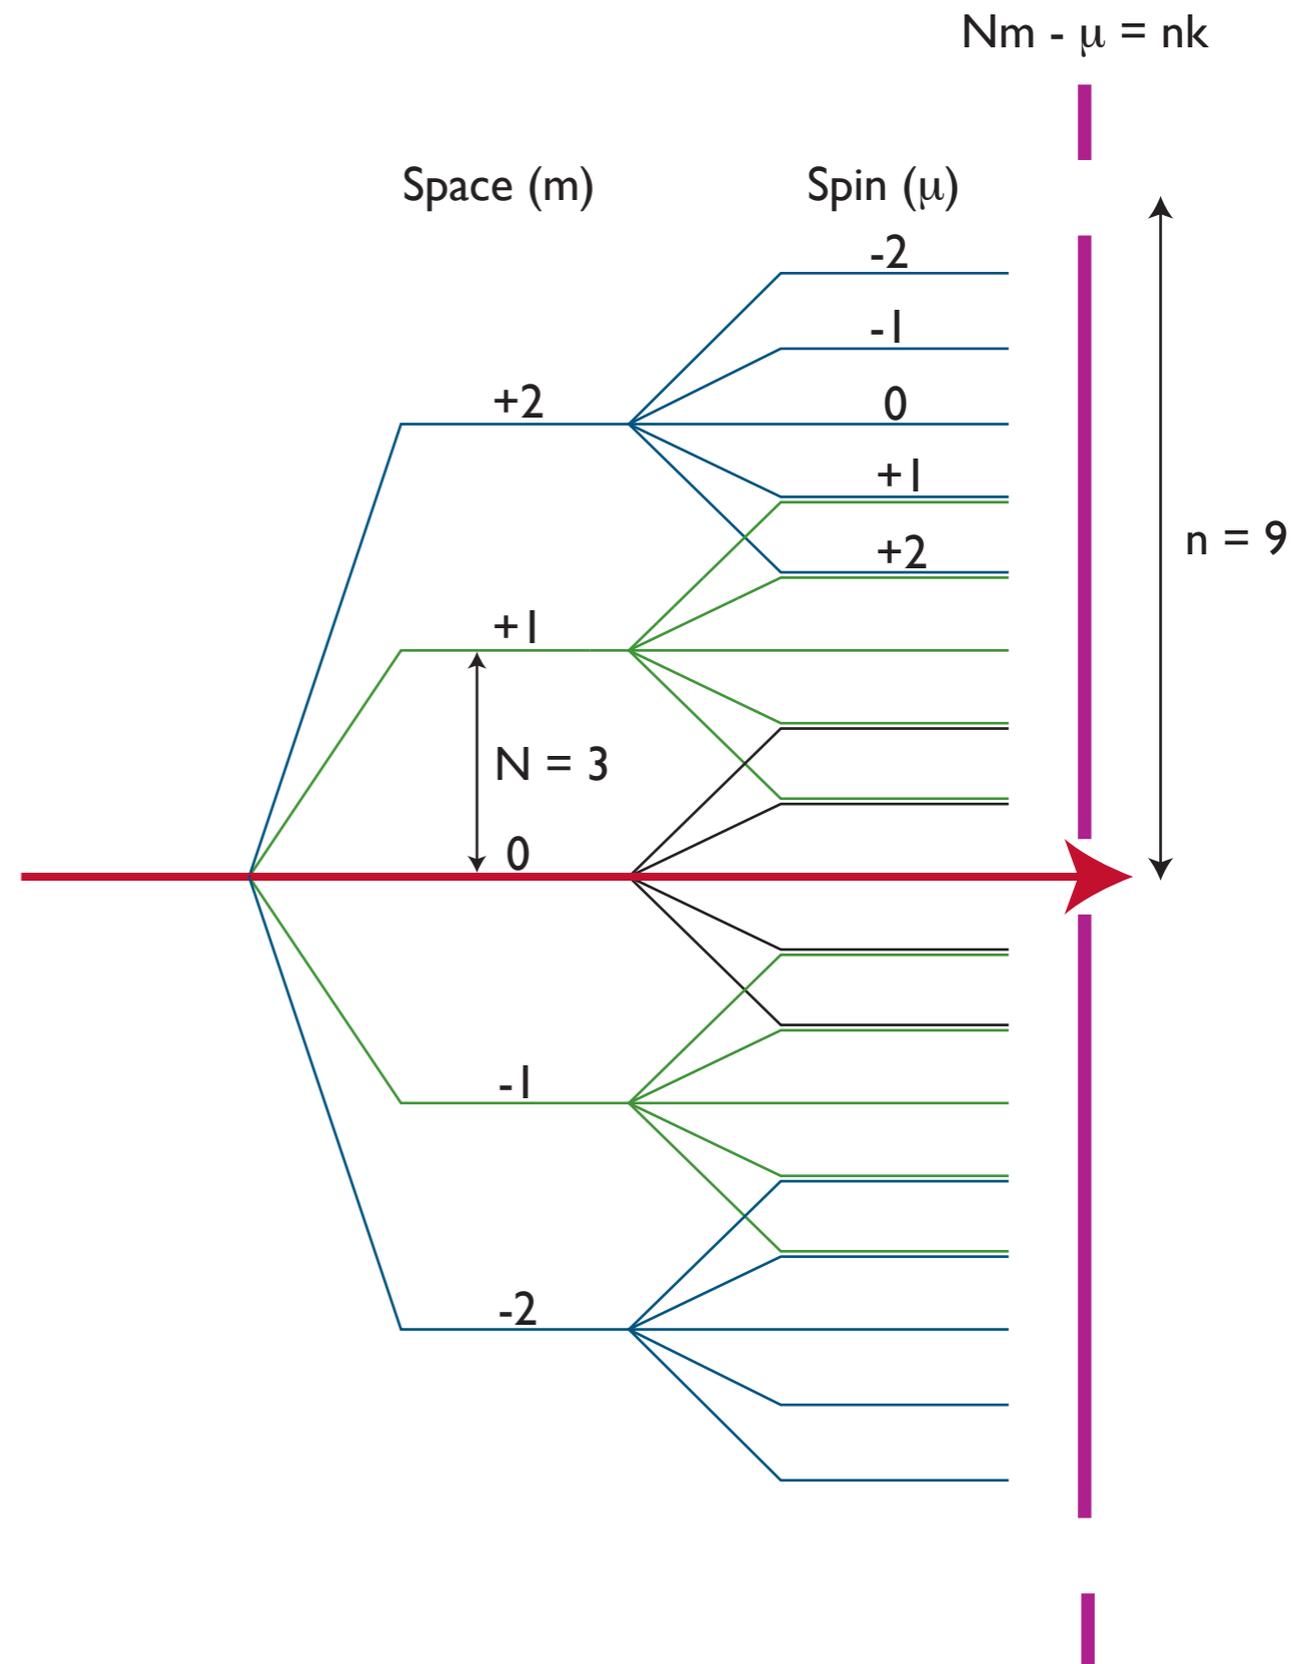

C9 sequence

The **spin-space selection diagram** illustrates which combinations of spin and space components are retained in the average Hamiltonian for the recoupling sequence.

The spin-space selection diagram shows that with $n = 9$ and $N = 3$ only space-spin $(m, \mu) = (0, 0)$ components are retained in the average Hamiltonian.

$$\bar{H}^{(0)} = 2\pi J \mathbf{I}_2 \cdot \mathbf{I}_2$$

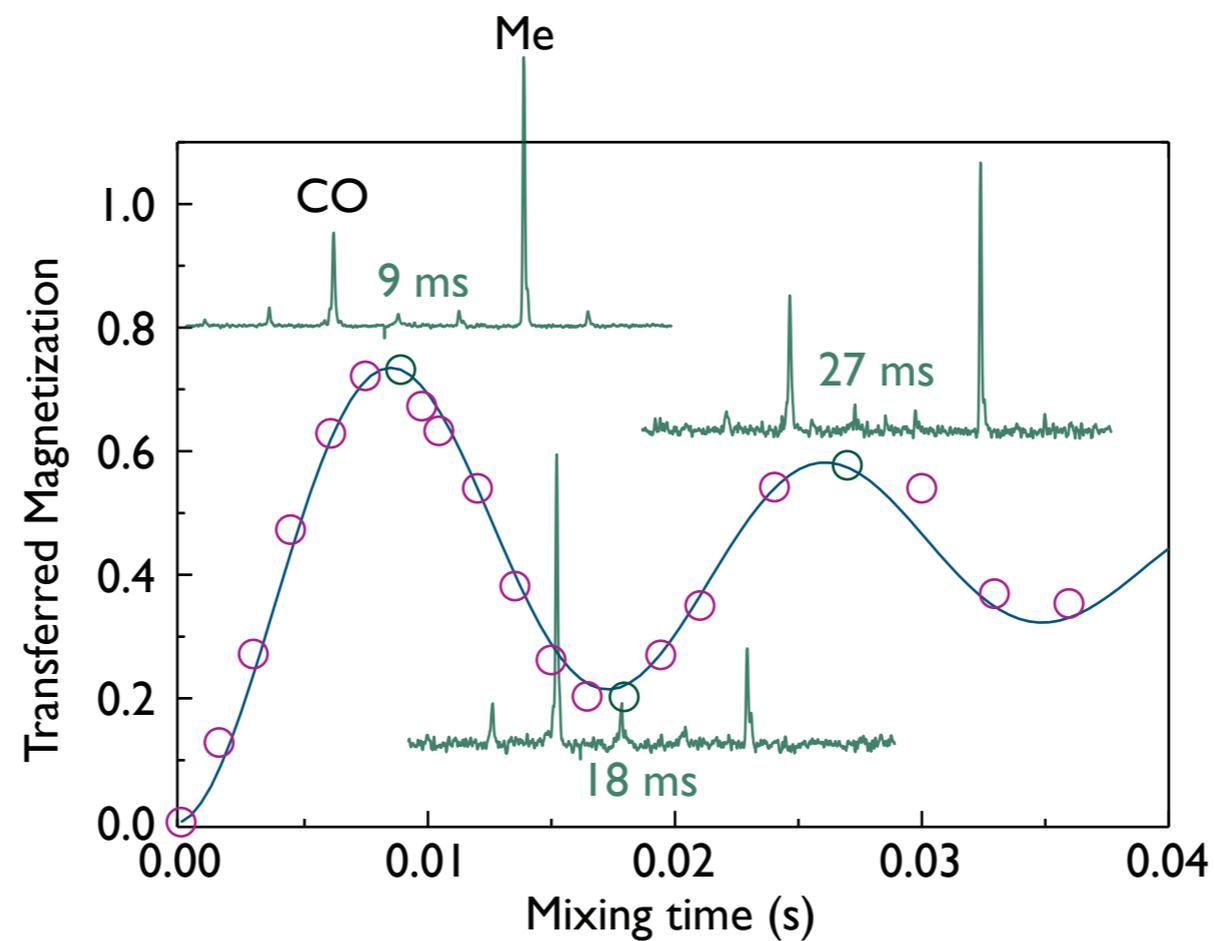

Isotropic mixing

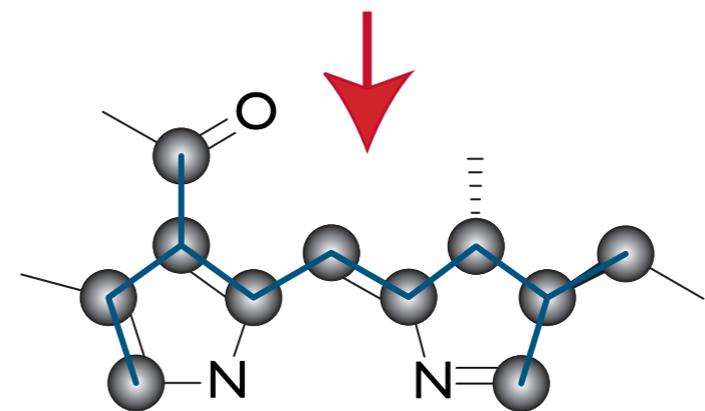

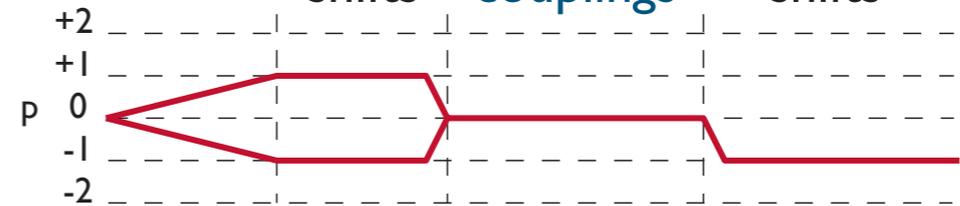

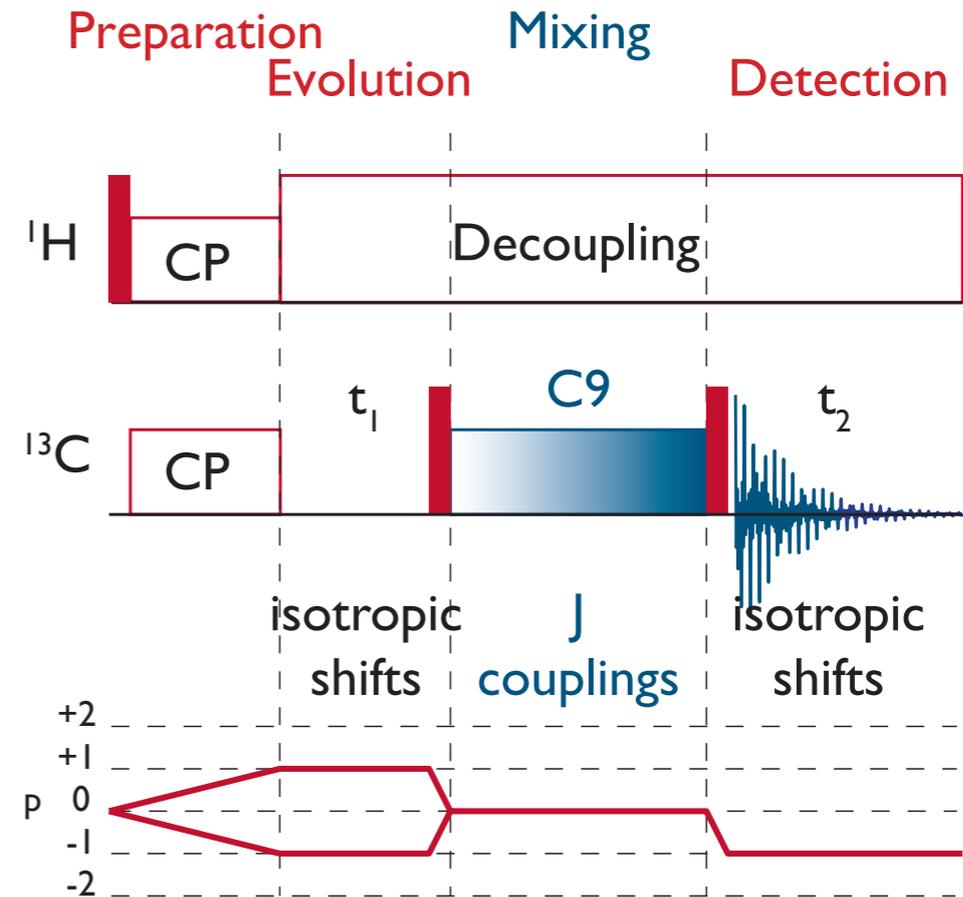

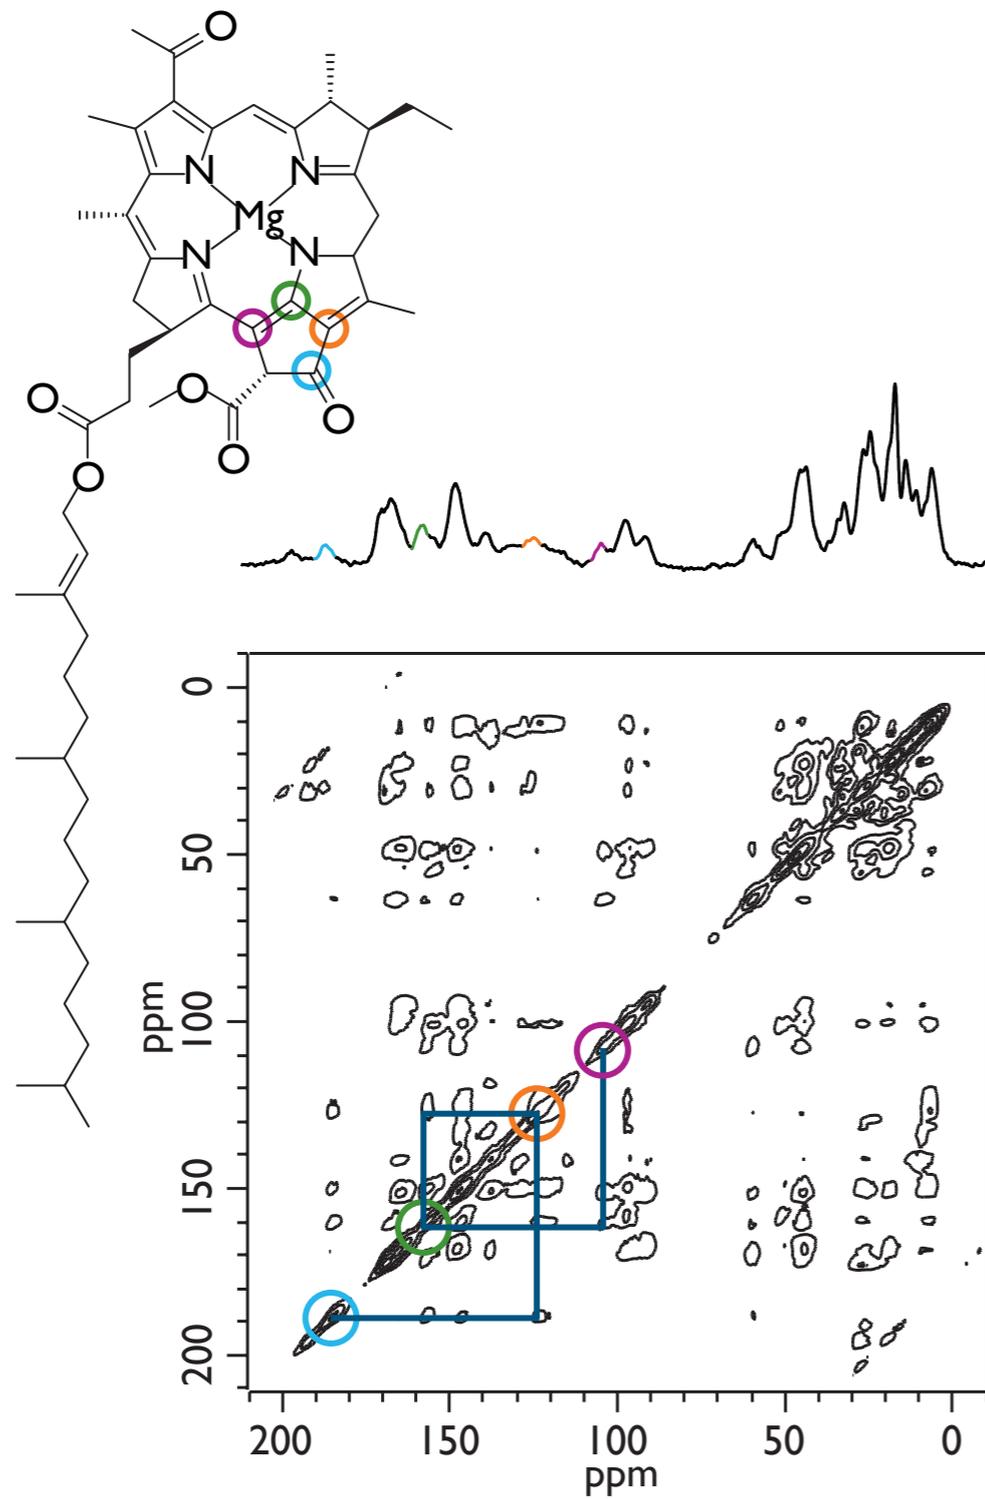

Isotropic mixing

The isotropic mixing Hamiltonian transfers magnetization directly between in-phase states. This is the basis of the solution-state TOCSY experiment.

$$\hat{I}_{1x} \xrightarrow{\hat{H}_{\text{iso}} = 2\pi J_{12} \hat{I}_1 \cdot \hat{I}_2} \hat{I}_{2x}$$

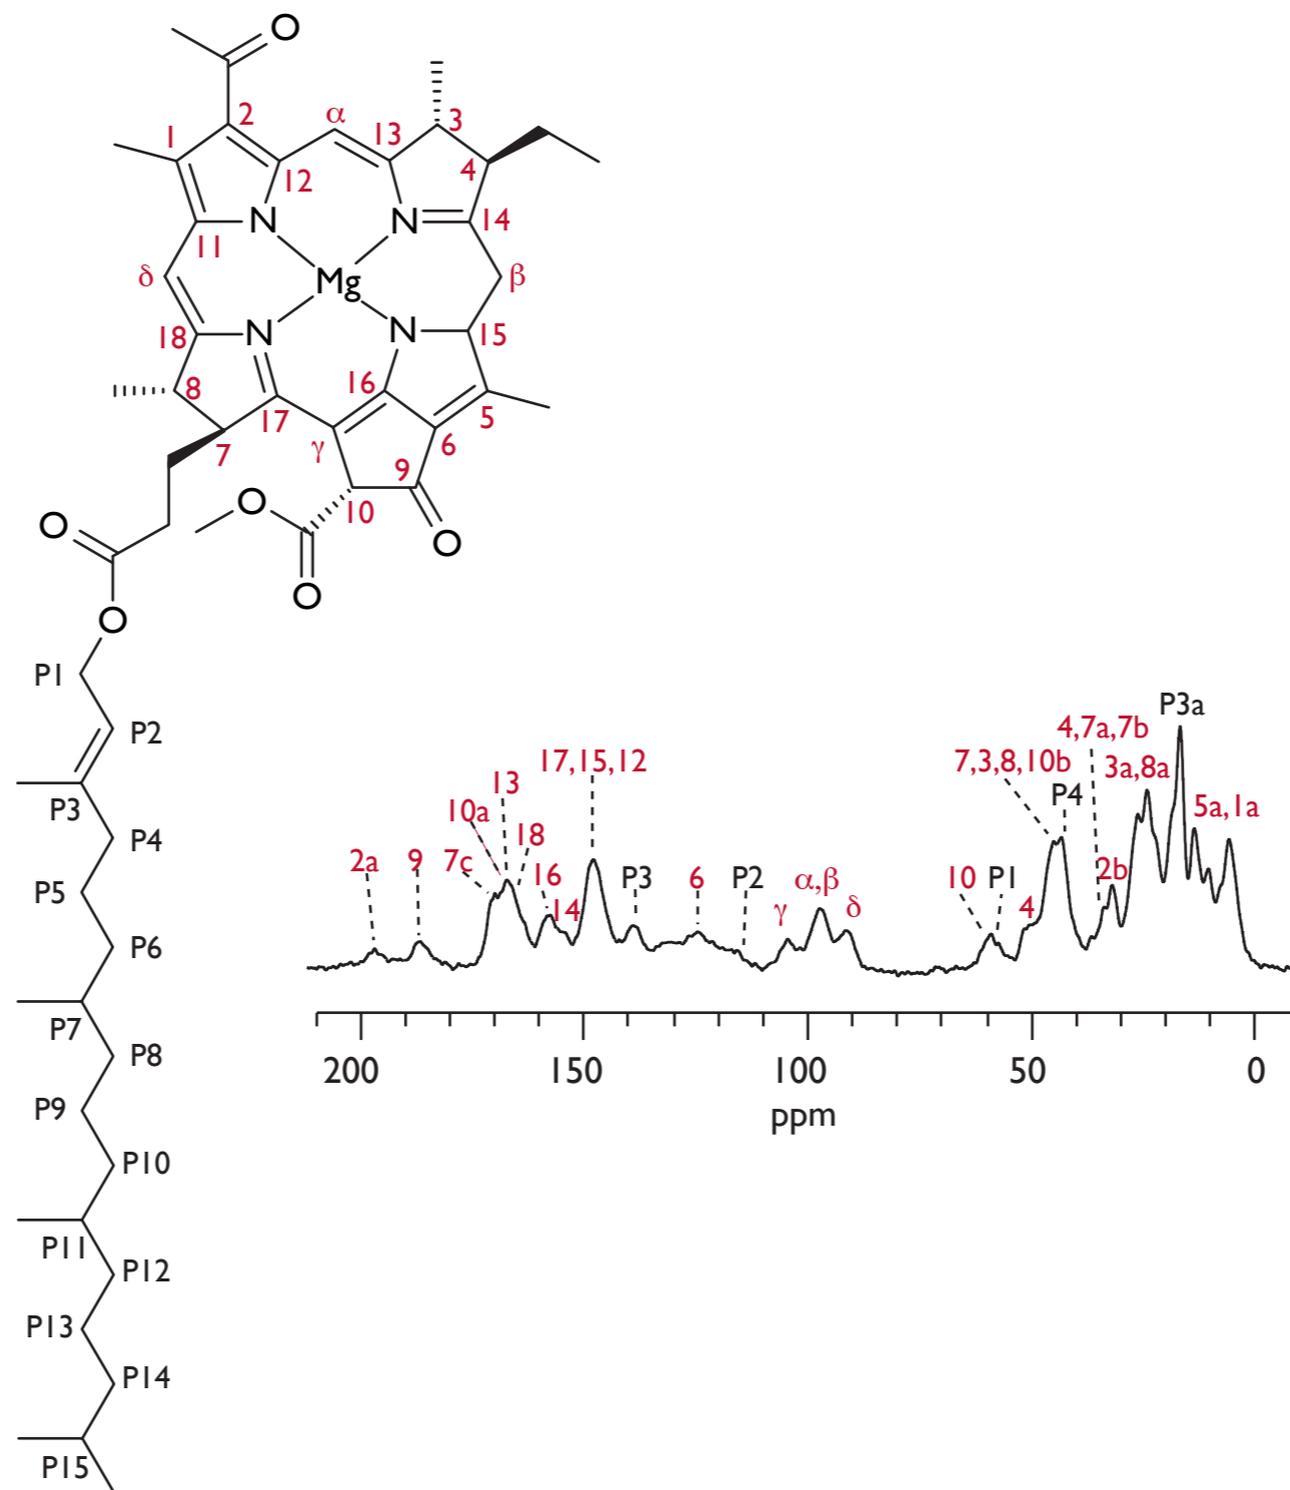

Scalar correlation

carbon-13
J couplings

Carbon-13 assignment

The combination of dipolar and scalar correlation information allows all the carbon-13 resonances to be assigned, with the exception of the mobile chain P5 - P15.

Mechanisms for dipolar transfer

Recoupled dipolar Hamiltonian

A pulse sequence during the mixing period recouples the double- or zero-quantum dipolar Hamiltonian. Both of these cause magnetization transfer between dipolar-coupled pairs of spins.

$$H_{ZQ} \propto 2I_{1z}I_{2z} - \frac{1}{2}(I_1^+I_2^- + I_1^-I_2^+)$$
$$H_{DQ} \propto (I_1^+I_2^+ + I_1^-I_2^-)$$

Proton driven spin diffusion

During the mixing period the decoupler is turned off so that magnetization is transferred between (carbon-13) spins via spin diffusion in the dipolar-coupled proton network.

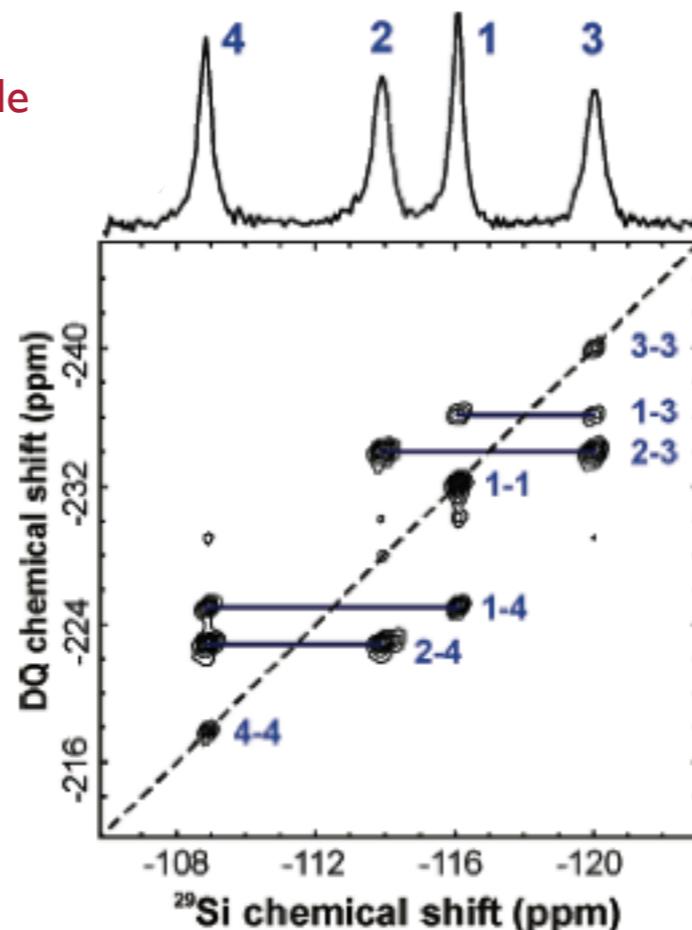

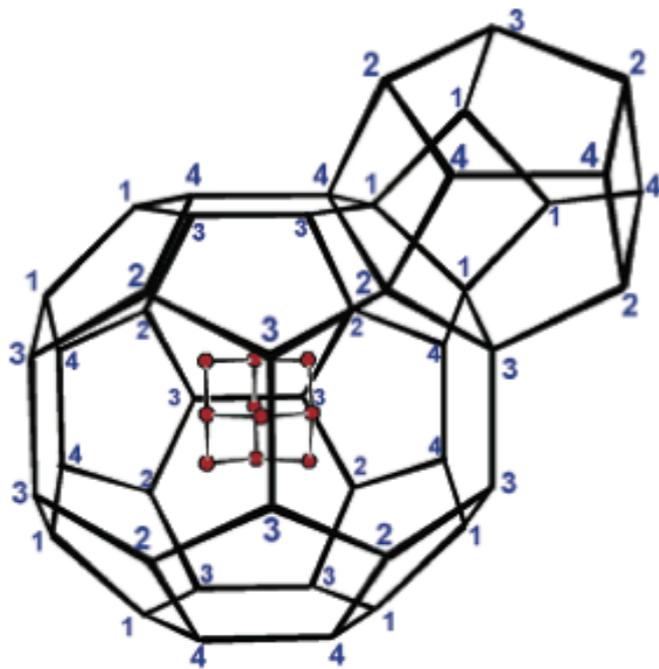

Cross polarization

In a heteronuclear correlation experiment the mixing period consists of a cross polarization step to transfer magnetization between heteronuclei. To ensure that magnetization is transferred only to near neighbors special cross polarization sequences must be used which eliminate proton dipolar couplings and prevent spin diffusion.

Zeolite framework structure

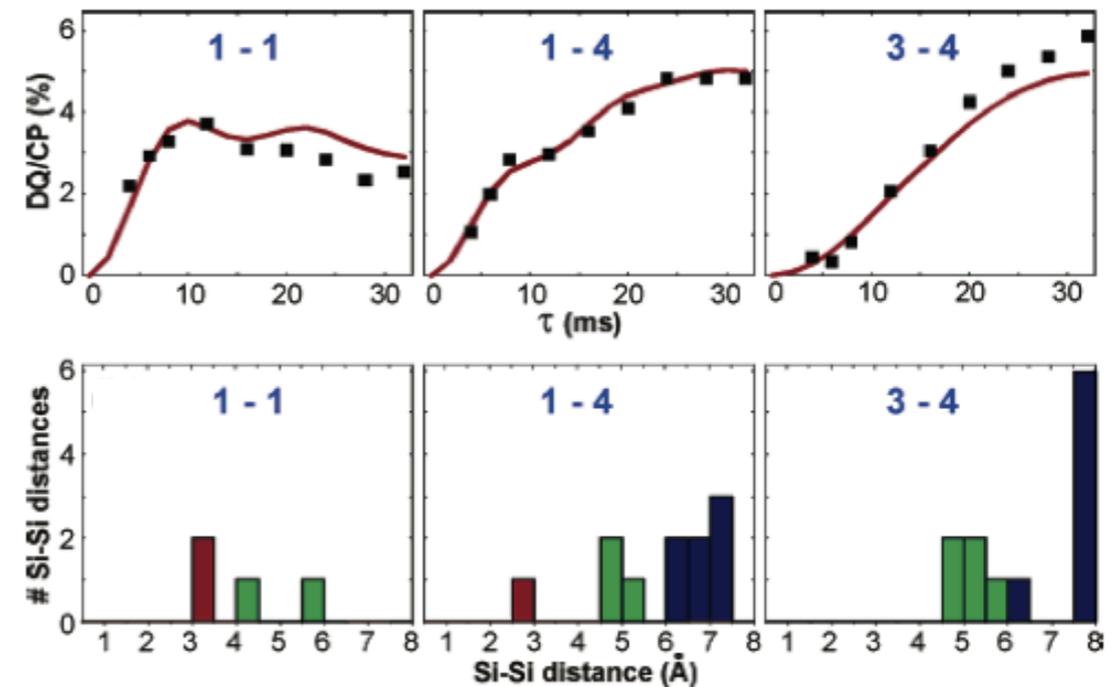

- ★ Zeolite framework structures are not easily solved by X-ray diffraction.
- ★ The SR264¹¹ recoupling sequence used in this silicon-29 dipolar correlation experiment is a robust method for recoupling weak homonuclear dipolar interactions while decoupling weak heteronuclear ones.
- ★ The resulting cross peak build up curves can be simulated in terms of a histogram of Si-Si distances which together with the lattice parameters and the space group from X-rays can be used to solve the zeolite framework structure.

Problems with dipolar correlations

Dipolar Truncation

In a multi-spin system the spin dynamics is dominated by the largest dipolar couplings which are often between bonded spins and of little use in studies of conformation (although they are very useful for making assignments).

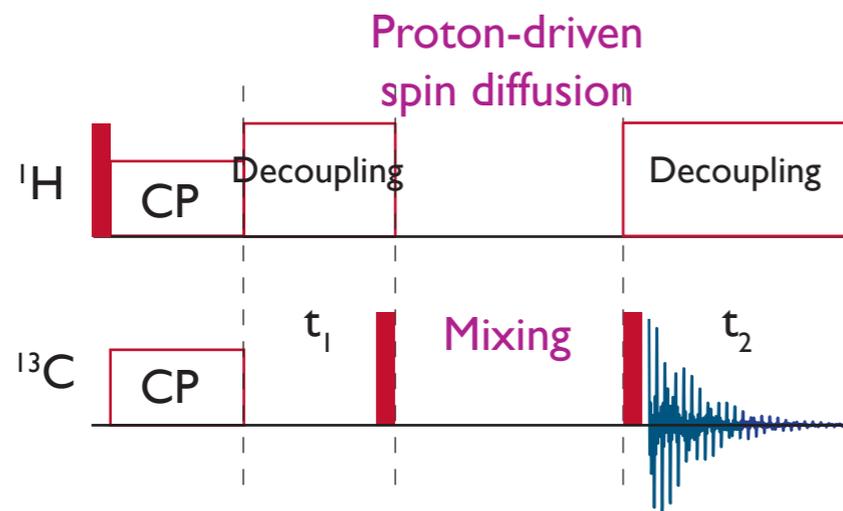

This makes the observation of long-range distance restraints difficult.

Dipolar truncation can be overcome by:

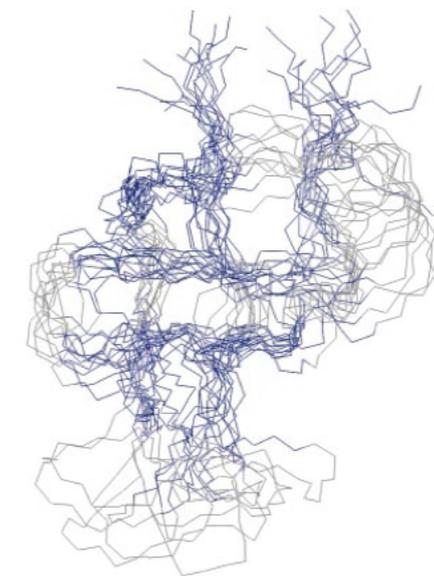

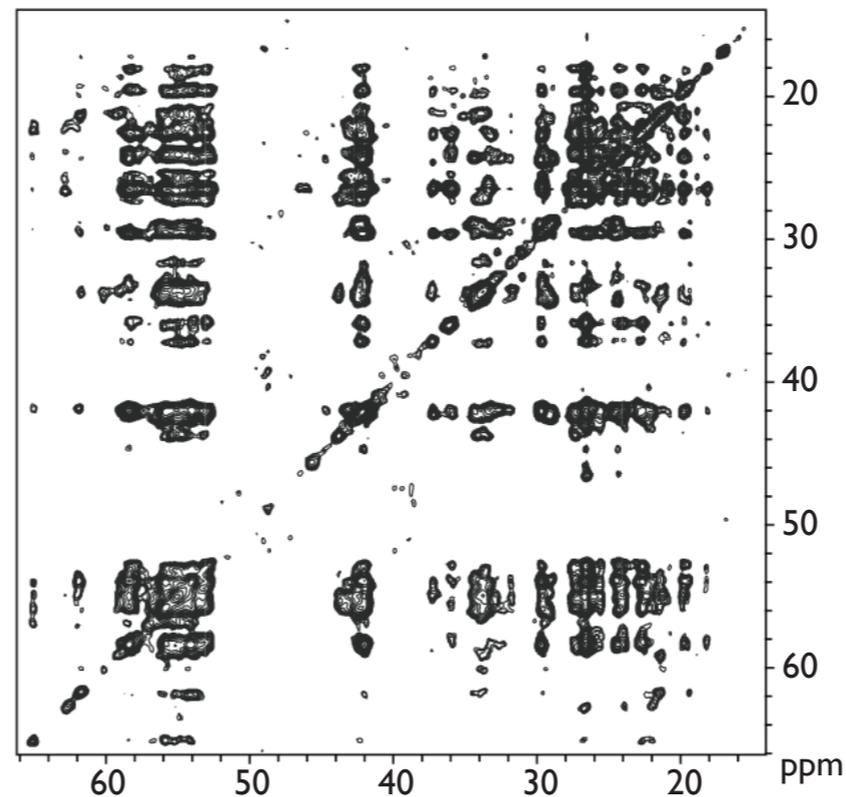

- ★ uniform labeling and frequency-selective recoupling
- ★ broadband recoupling and restricted labeling

Structure of SH3 by PDSD

- ★ This study used a micro-crystalline preparation of the α -spectrin Src-homology 3 (SH3) domain.
- ★ Proton-driven ^{13}C - ^{13}C spin diffusion spectra were obtained from biosynthetically site-directed labelled samples obtained from bacteria grown on $[1,3\text{-}^{13}\text{C}_2]\text{glycerol}$ or $[2\text{-}^{13}\text{C}]\text{glycerol}$.
- ★ This labeling strategy reduces dipolar truncation and hence allowed 286 inter-residue ^{13}C - ^{13}C restraints to be extracted from the spectra.
- ★ Distances were estimated by measuring the build-up of cross peak intensity as a function of mixing time and comparing this with conformation independent reference distances.

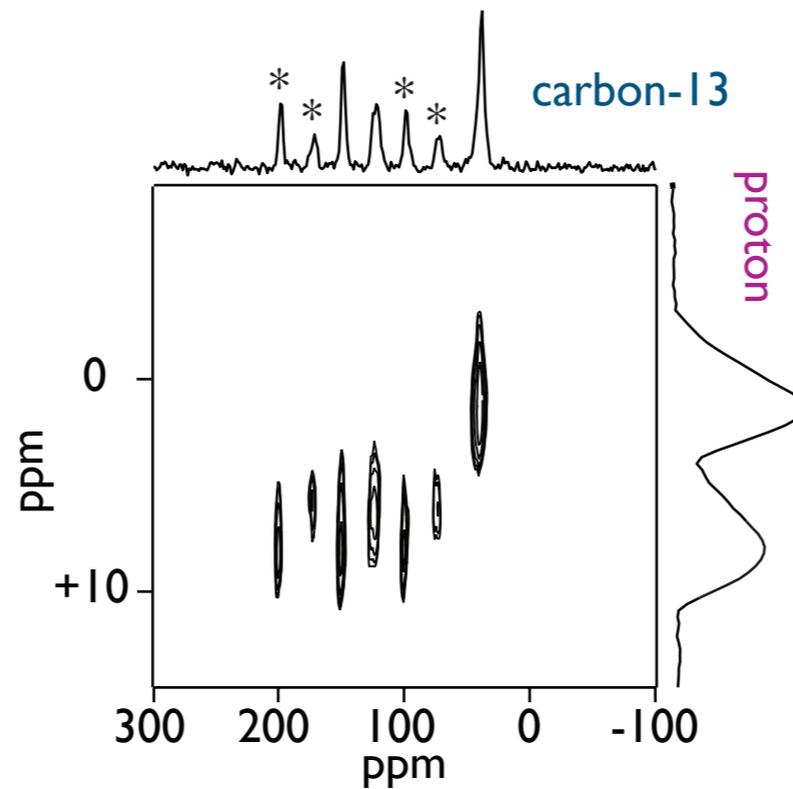

carbon-13 PDSD spectrum

structure by solid-state NMR

Heteronuclear correlation experiments

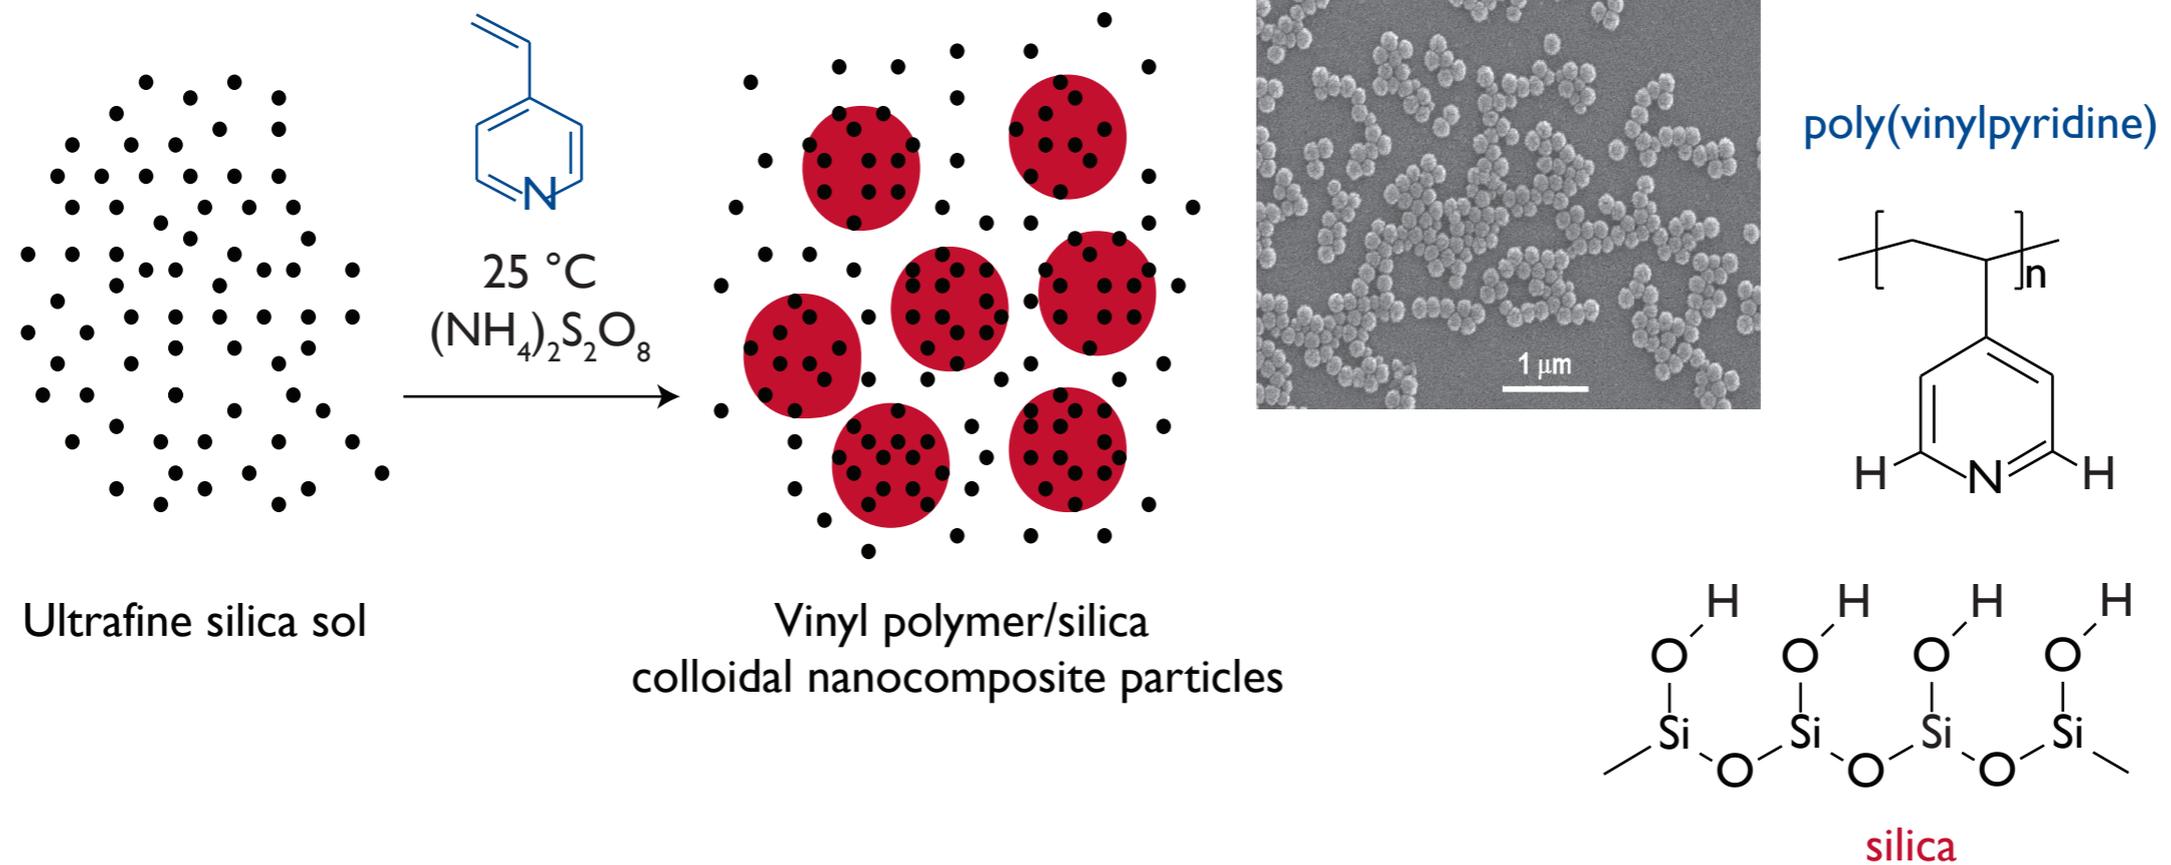

- ★ The high-resolution spectra which are observed in ν_1 and ν_2 correspond to different nuclei.
- ★ The mixing period involves heteronuclear magnetization transfer.

Nature of the interface in PVP-silica nanocomposites

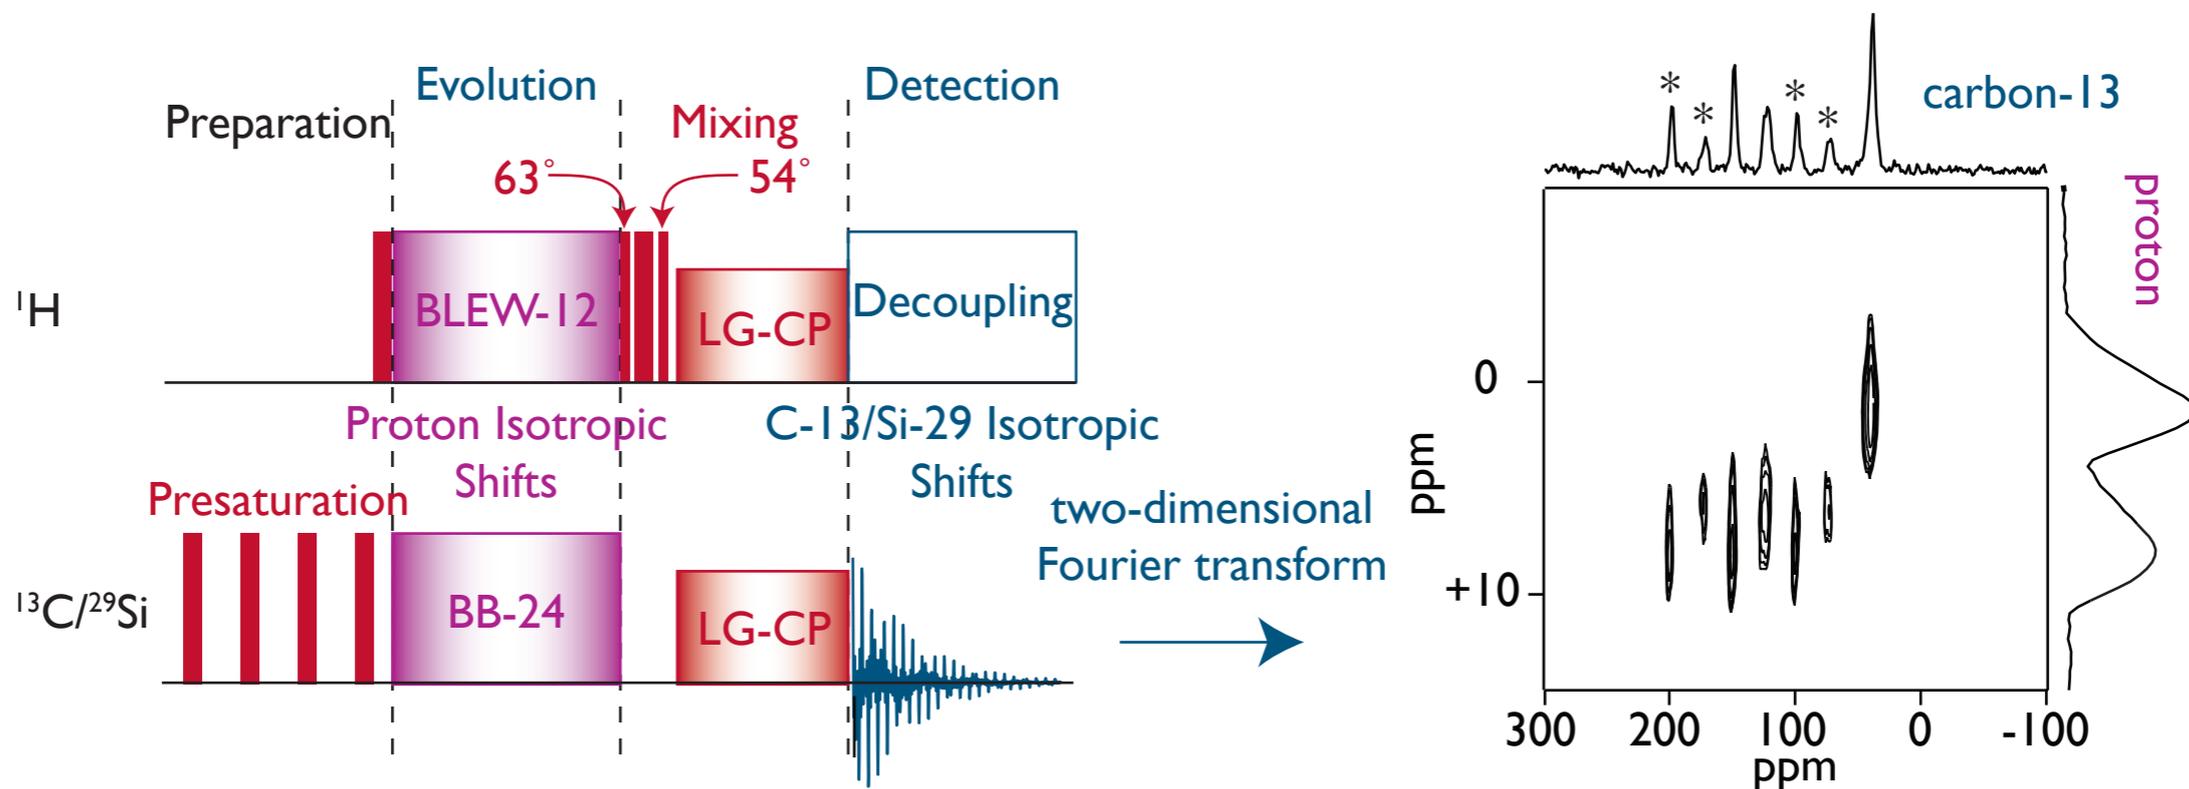

- ★ Vinyl pyridine is polymerized in the presence of an aqueous silica sol to produce nanocomposite particles 200 nm in diameter.
- ★ Inorganic phase adds mechanical strength, fire retardancy etc. to the polymer.

What is the nature of the interaction between the inorganic and organic phases?

BLEW-LGCP heteronuclear correlation

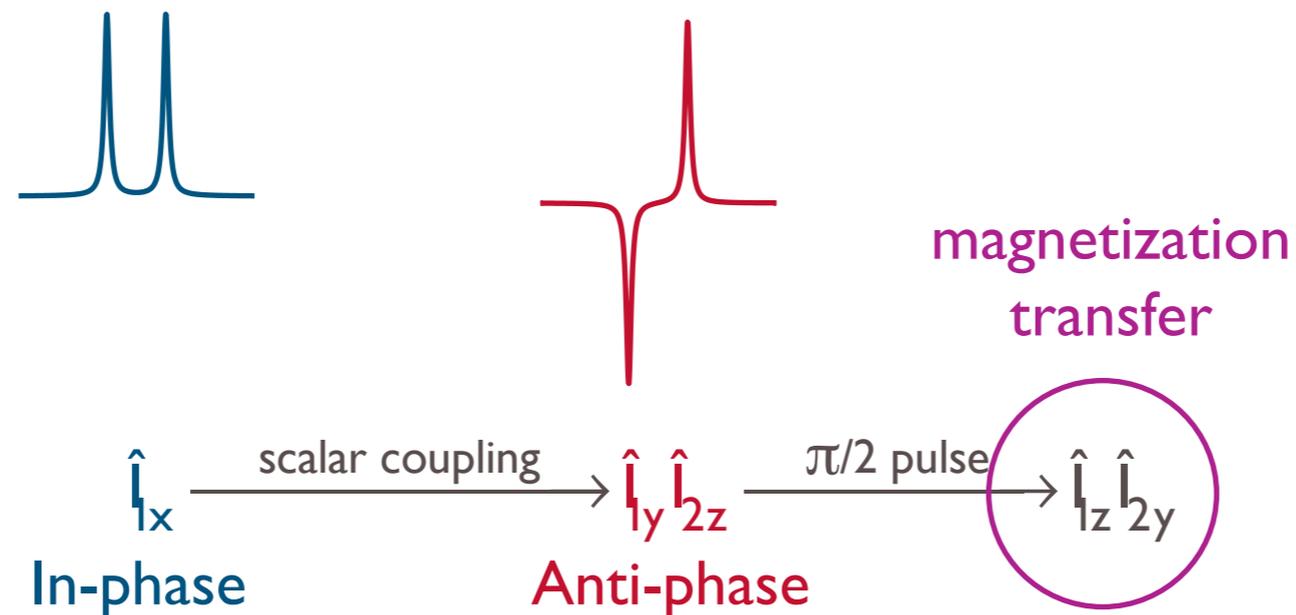

- ★ The **preparation** period involves presaturation to ensure that no carbon-13/silicon-29 magnetization is present at the start of the experiment
- ★ In the **evolution** period the experiment measures the high-resolution proton spectrum obtained using CRAMPS (in this case the BLEW-12 windowless decoupling sequence). Note the use of the BB-24 sequence on carbon-13/silicon-29 to decouple these spins from the protons.
- ★ During the **mixing** period a selective cross polarization scheme (in this case Lee-Goldberg CP) is used to transfer the proton magnetization to near neighbor carbon-13/silicon-29 spins.
- ★ In the **detection** period the experiment measures the high-resolution carbon-13/silicon-29 spectrum using decoupling.

Mechanisms for scalar transfer

Anti-phase magnetization

Solution-state scalar correlation experiments like COSY and INADEQUATE rely on the generation of magnetization which is anti-phase with respect to the active J coupling.

Isotropic mixing

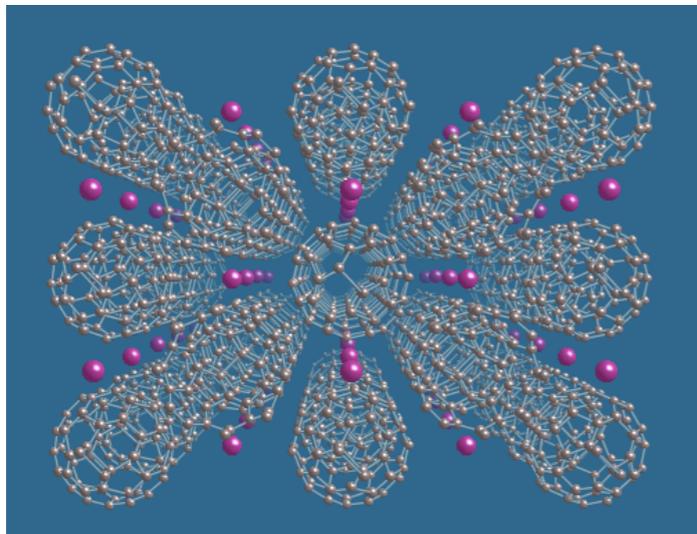

The isotropic mixing Hamiltonian transfers magnetization directly between in-phase states. This is the basis of the solution-state TOCSY experiment.

$$\hat{I}_x \xrightarrow{\hat{H}_{\text{iso}} = 2\pi J \mathbf{I}_1 \cdot \mathbf{I}_2} \hat{I}_{2x}$$

Linewidths in MAS spectra

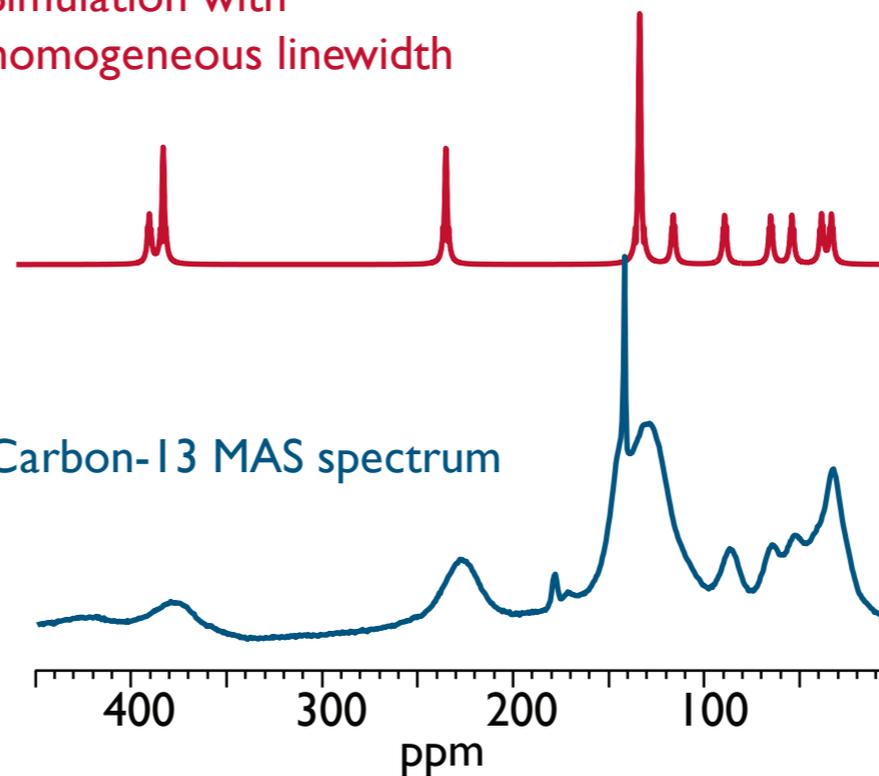

In solids even for dilute spin-1/2 nuclei with MAS and decoupling the NMR linewidth is significantly broader than in solution due to:

- ★ **Homogeneous contributions.** These arise from incomplete decoupling or molecular motion.
- ★ **Inhomogeneous contributions.** These arise from an inhomogeneous B_0 field or shift distributions due to sample heterogeneity. They can be refocused by a spin echo.

measurement

Effect on cross peak sensitivity

When J is within the linewidth the multiplet components cancel and experiments based on anti-phase magnetization transfer have very low sensitivity.

Solid-state scalar correlation experiments are usually “refocused” so that the cross peaks are in-phase, resulting in a significant improvement in sensitivity since the multiplet components reinforce.

SAR-COSY

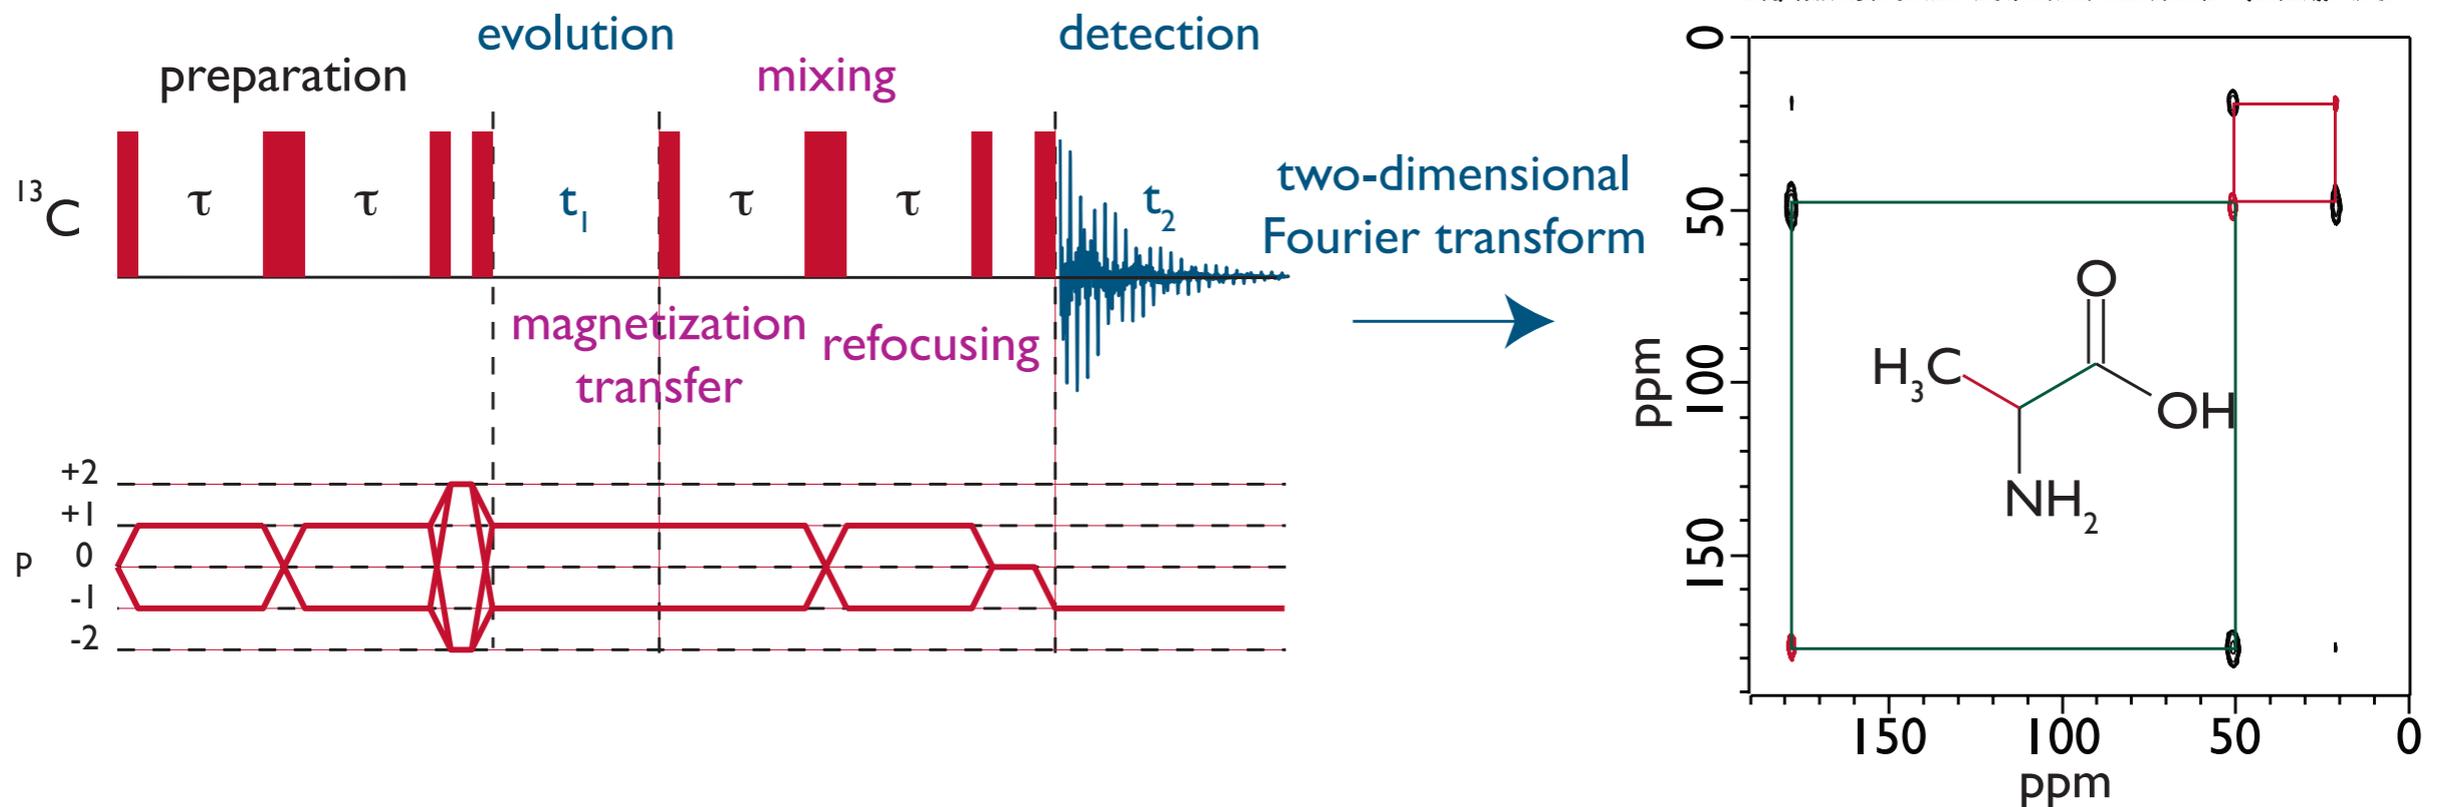

Sensitive, Absorptive, Refocused-COSY

Magnetization transfer occurs via anti-phase magnetization which is refocussed during the mixing period, so that the cross peaks are in-phase and absorptive in both dimensions. This maximizes sensitivity when J is within the linewidth.

The diagonal peaks are anti-phase and dispersive in ν_1 which means they have low intensity and their intensities vary with the preparation time according to:

$$\sin(2\pi J\tau) \cos(2\pi J\tau)$$

which is zero when $\tau = 1/(4J)$.

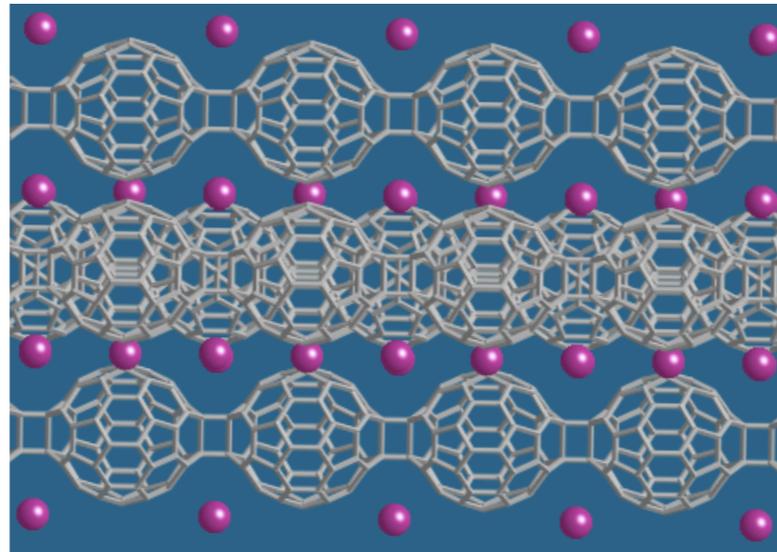

Alkali fullerides

CsC₆₀, RbC₆₀

These materials show interesting phase transitions:

- ★ the high temperature phase is fcc with alkali metals in octahedral interstices
- ★ the low temperature phase is formed from a reversible solid-state transformation which involves a shortening of the a lattice dimension

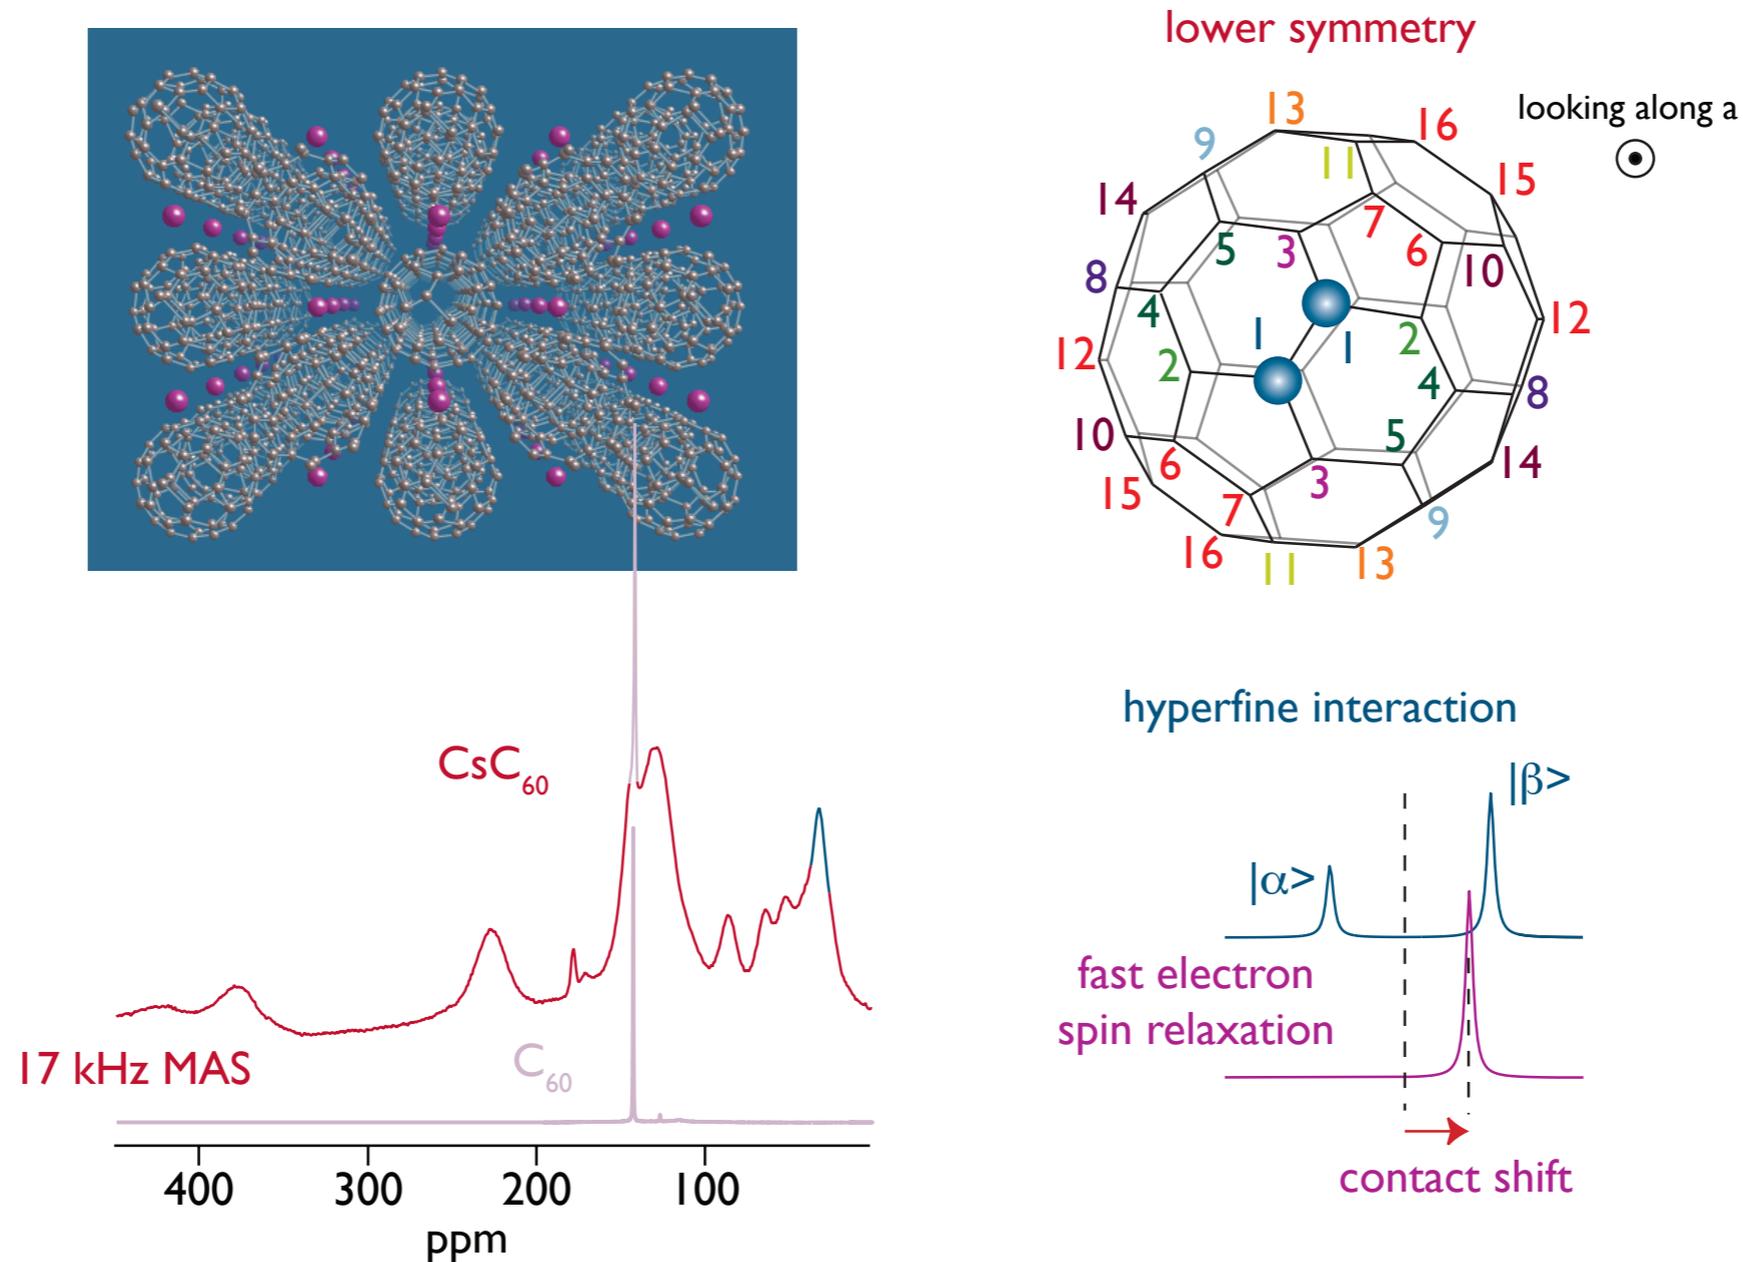

The inter-fullerene distance along a is only 9.138 Å which suggests the formation of polymeric C₆₀ chains by a 2+2 cyclo-addition reaction.

Carbon-13 MAS NMR of CsC₆₀

The polymerization reaction lowers the symmetry, resulting in 16 inequivalent carbon sites.

The hyperfine interaction with the unpaired electron donated from the caesium atom results in contact shifts.

50% U-¹³C CsC₆₀

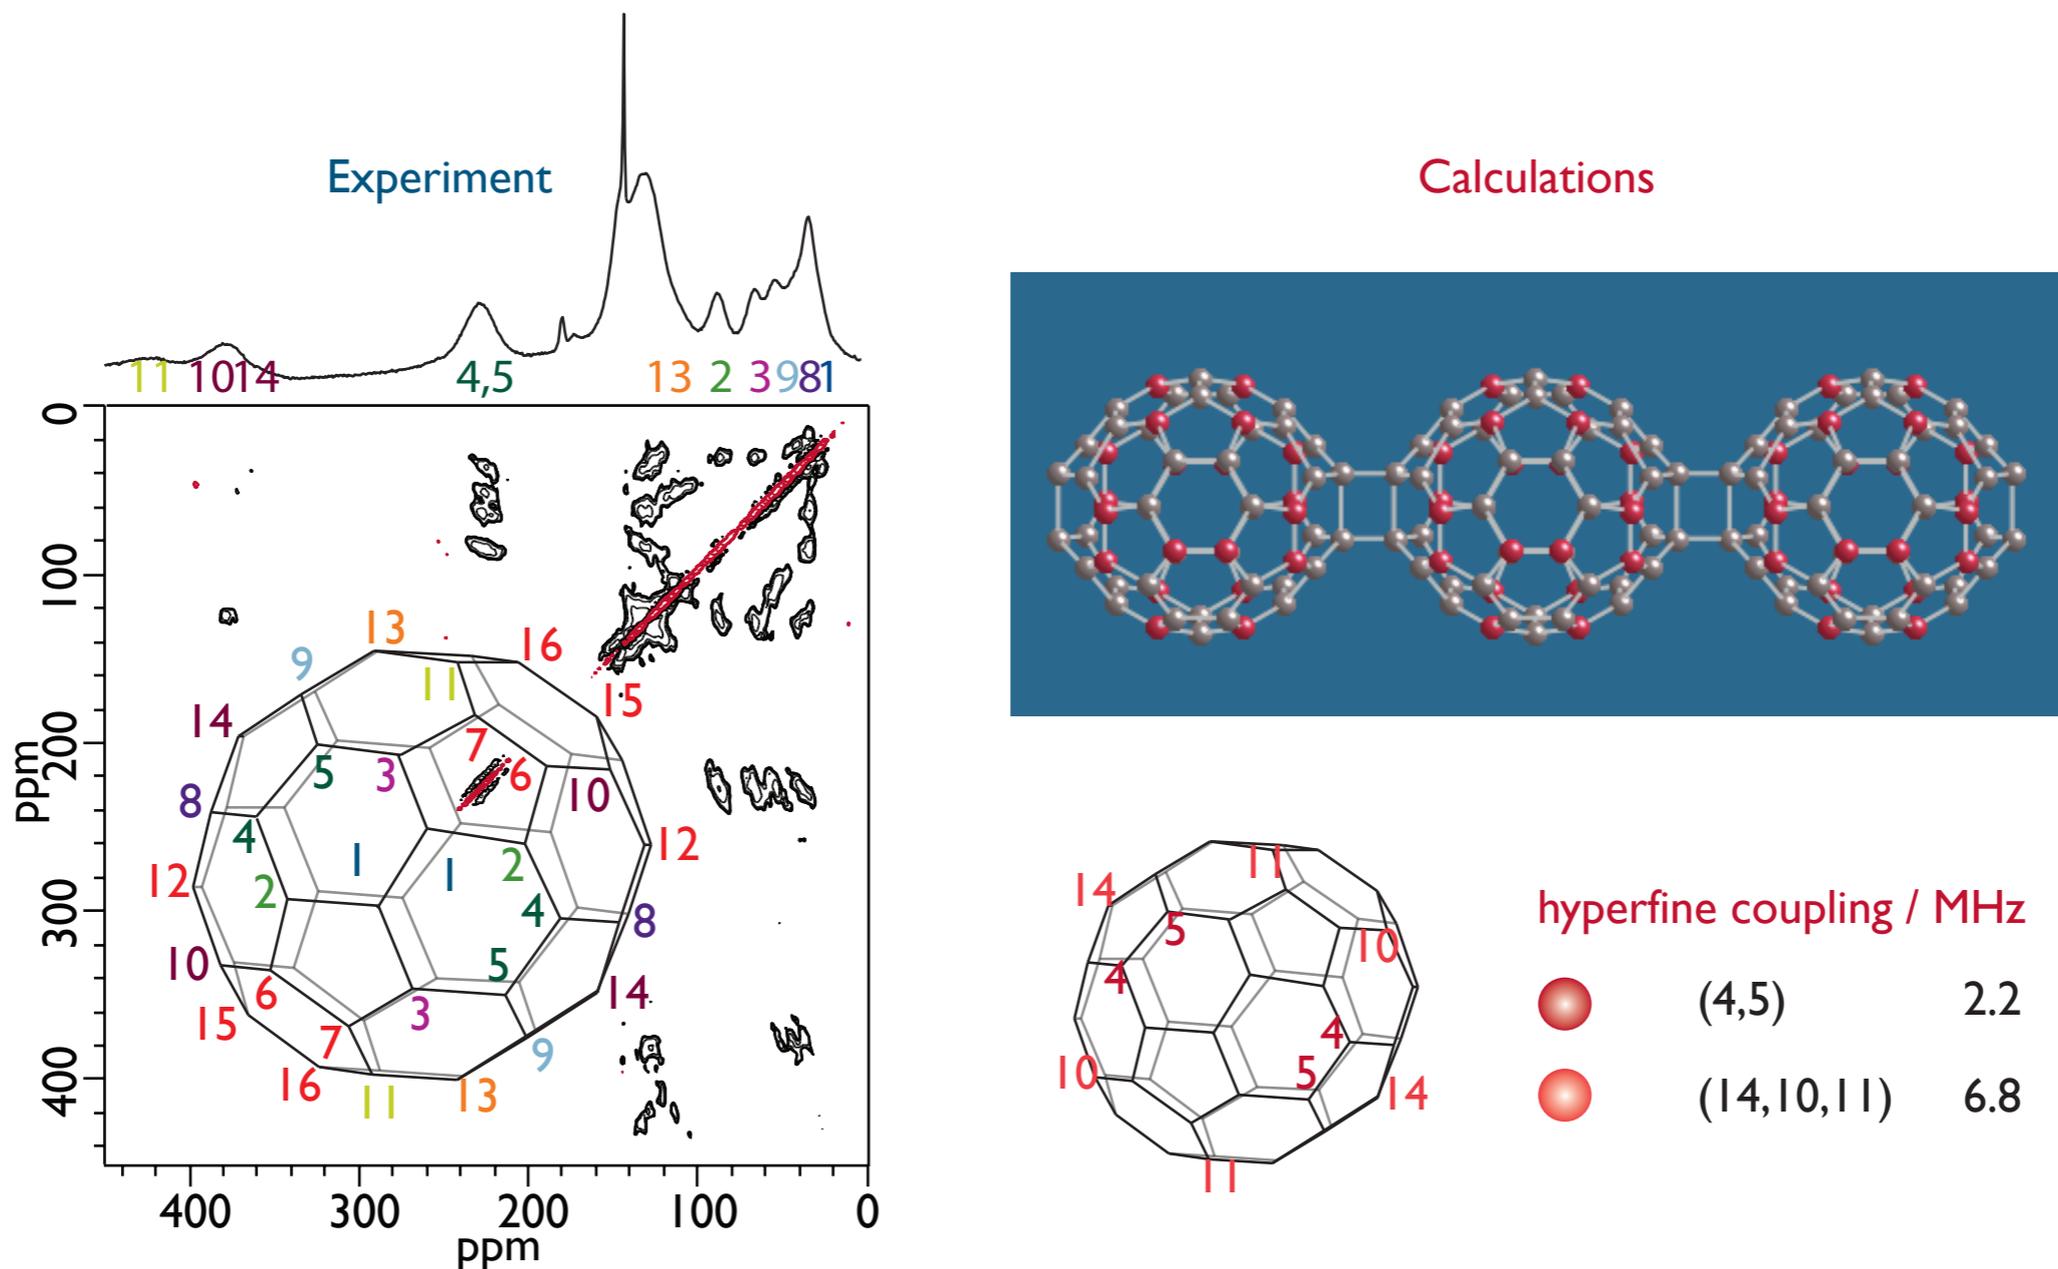

Carbon-13 enriched amorphous carbon packed into graphite tubes; 60 A 25 V dc arc between enriched rods under 3 psi He; Enriched C₆₀ and Cs mixed and heated for 1 week at 350 °C

Comparison with DFT calculations

Starting from the aliphatic inter-fullerene linkage (I) all the **experimental** carbon-13 lines can be assigned.

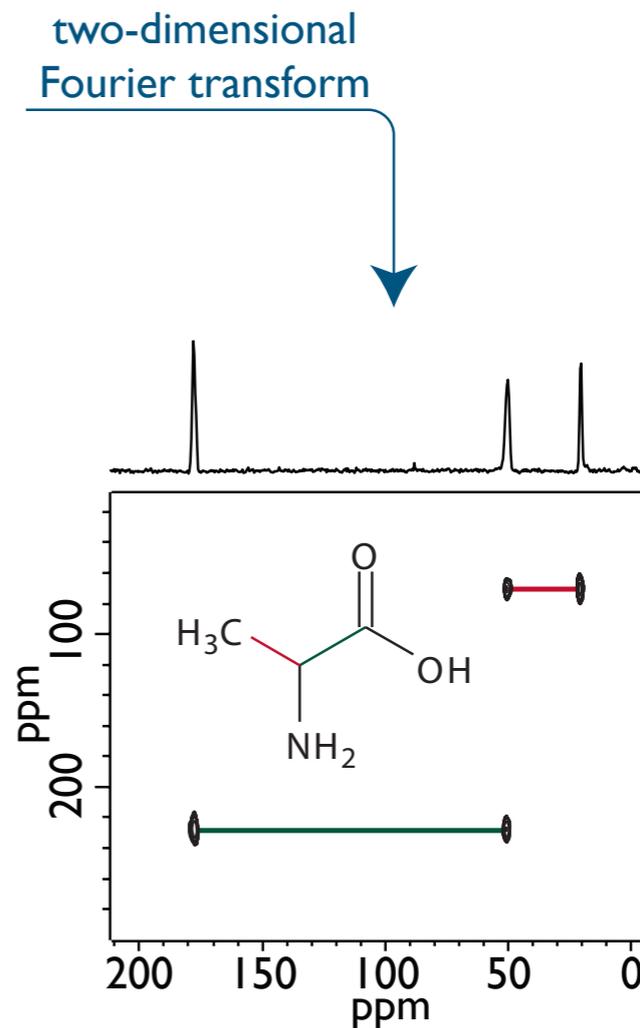

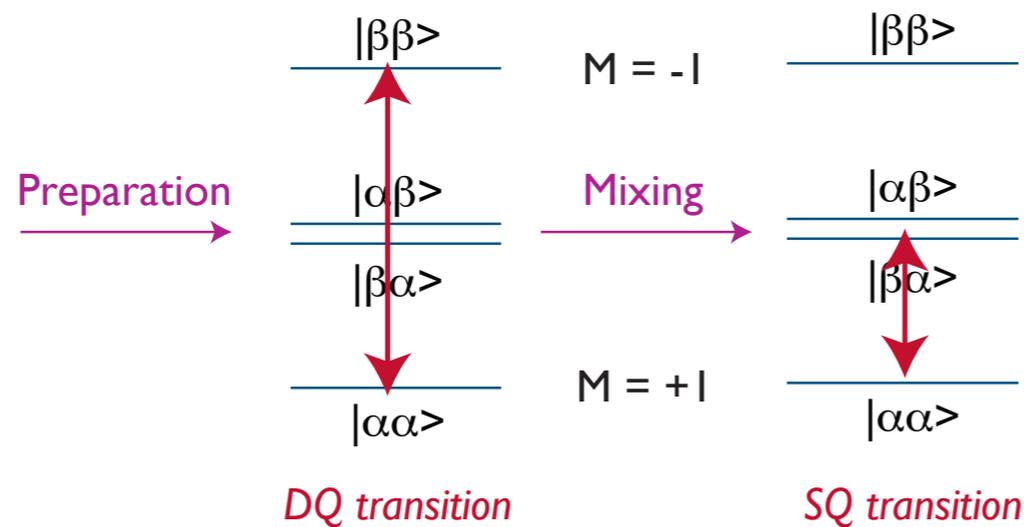

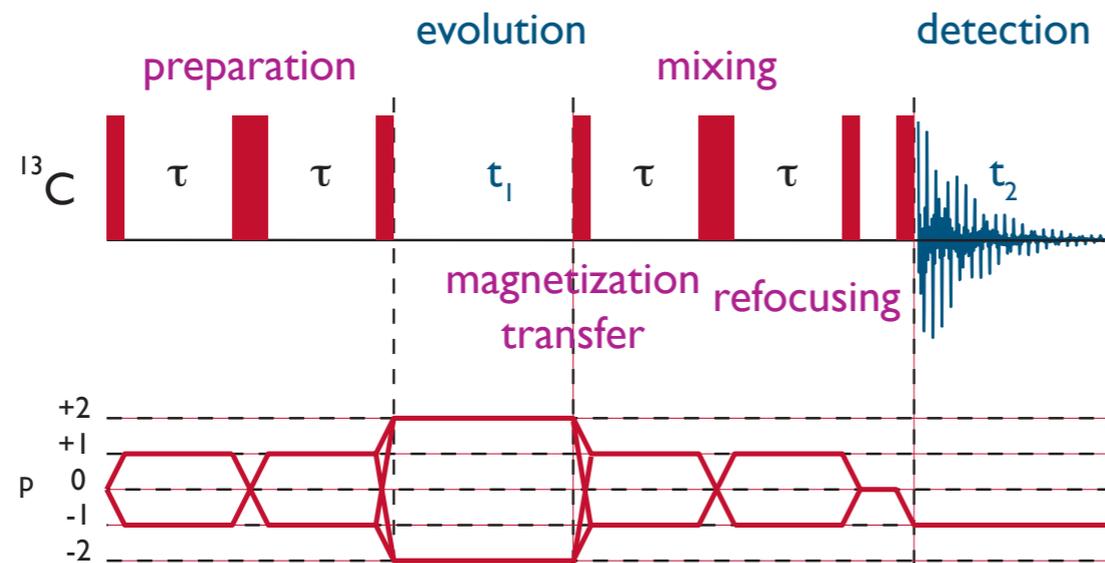

DFT **calculations** on a C₆₀ trimer based on the 3D semi-metal band structure show two groups of carbon sites with large hyperfine couplings.

These are the lines which show the largest experimental contact shifts, so the **3D semi-metal** is the correct model.

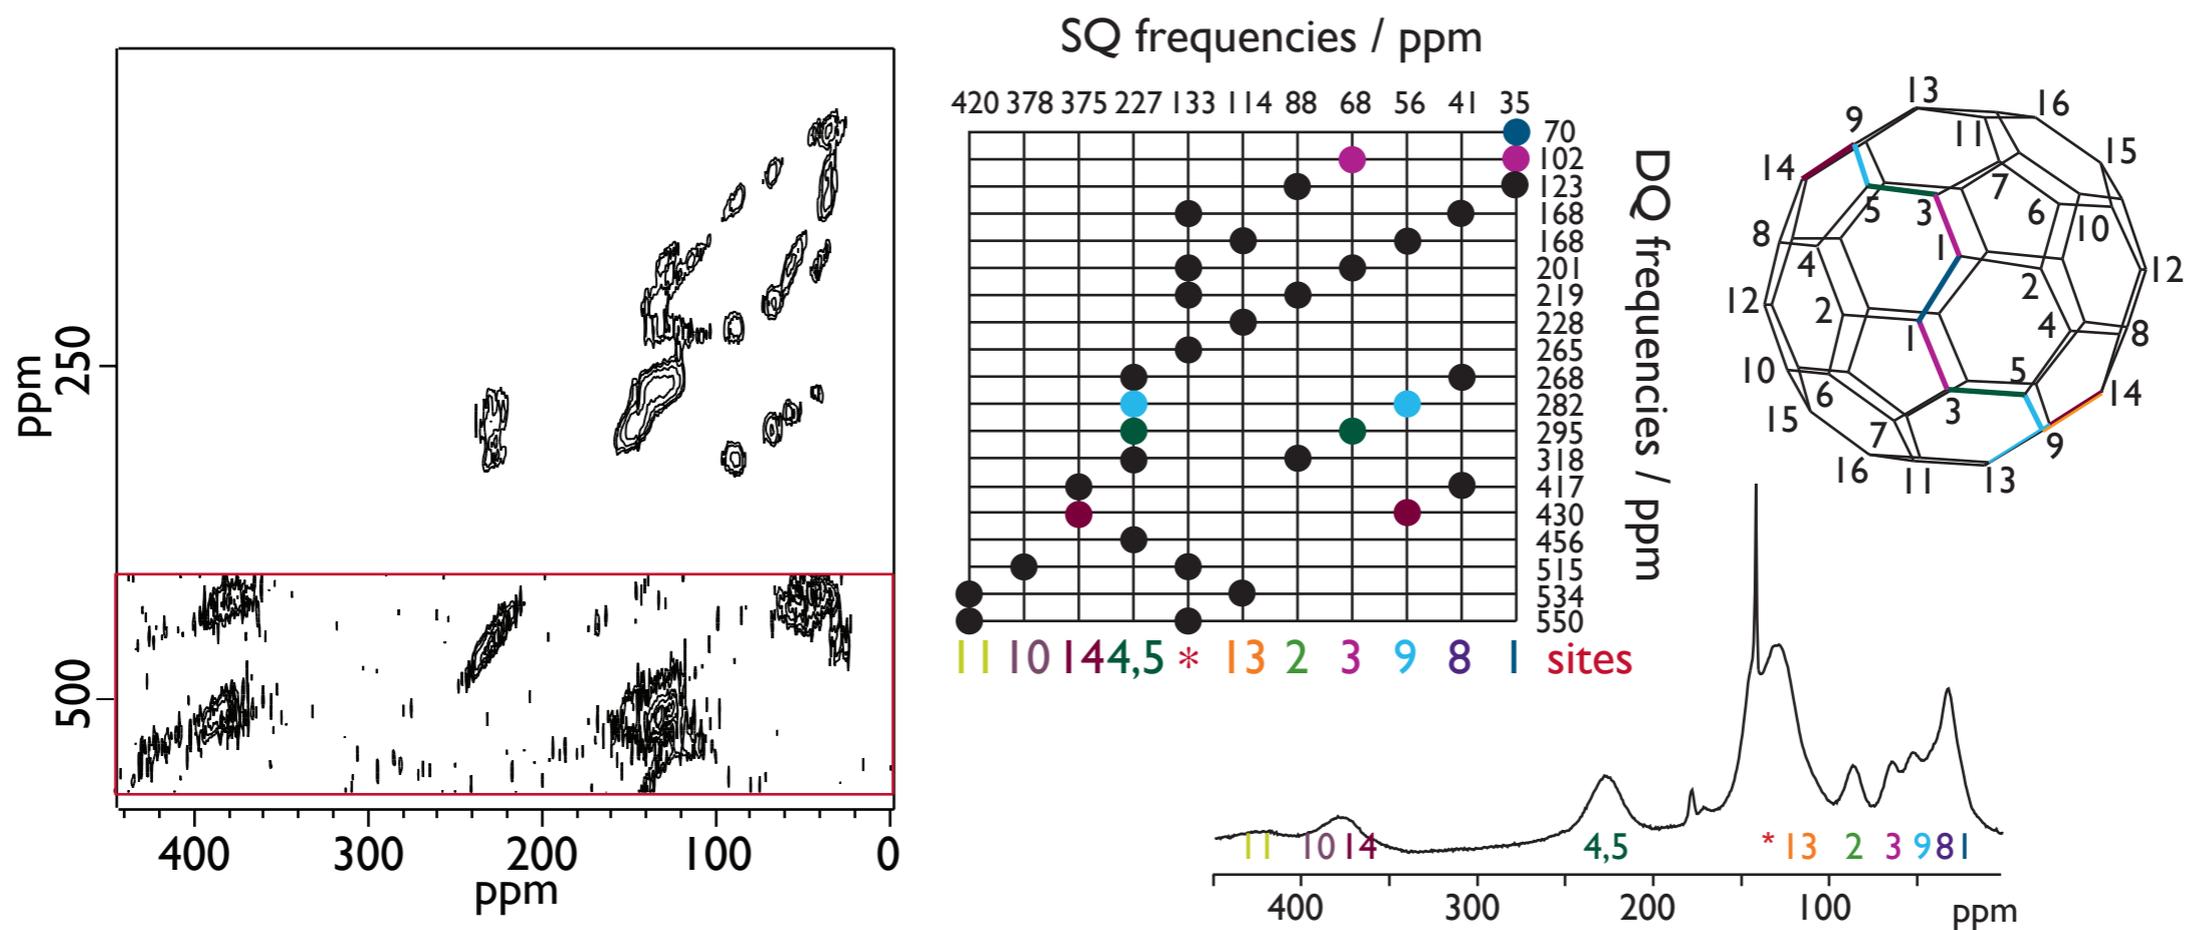

Refocused INADEQUATE

- ★ During the **preparation** period unobservable double-quantum coherences are excited.
- ★ These evolve at the sum of the chemical shifts of the spins involved in the **evolution** period.
- ★ They are reconverted to observable anti-phase magnetization which is refocussed during the **mixing** period, so that the peaks are in-phase and absorptive.

Comparison of methods

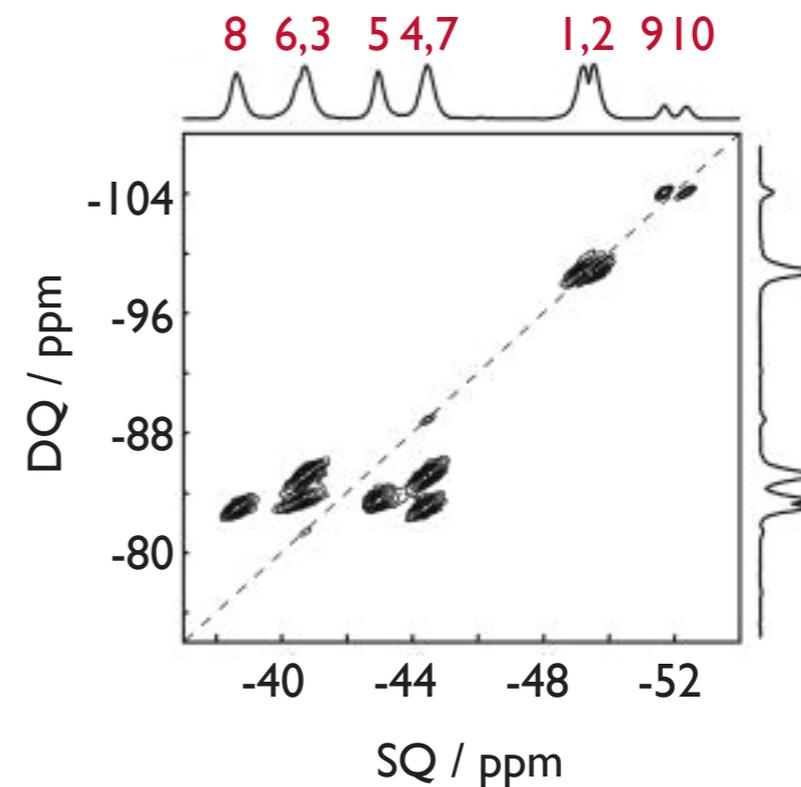

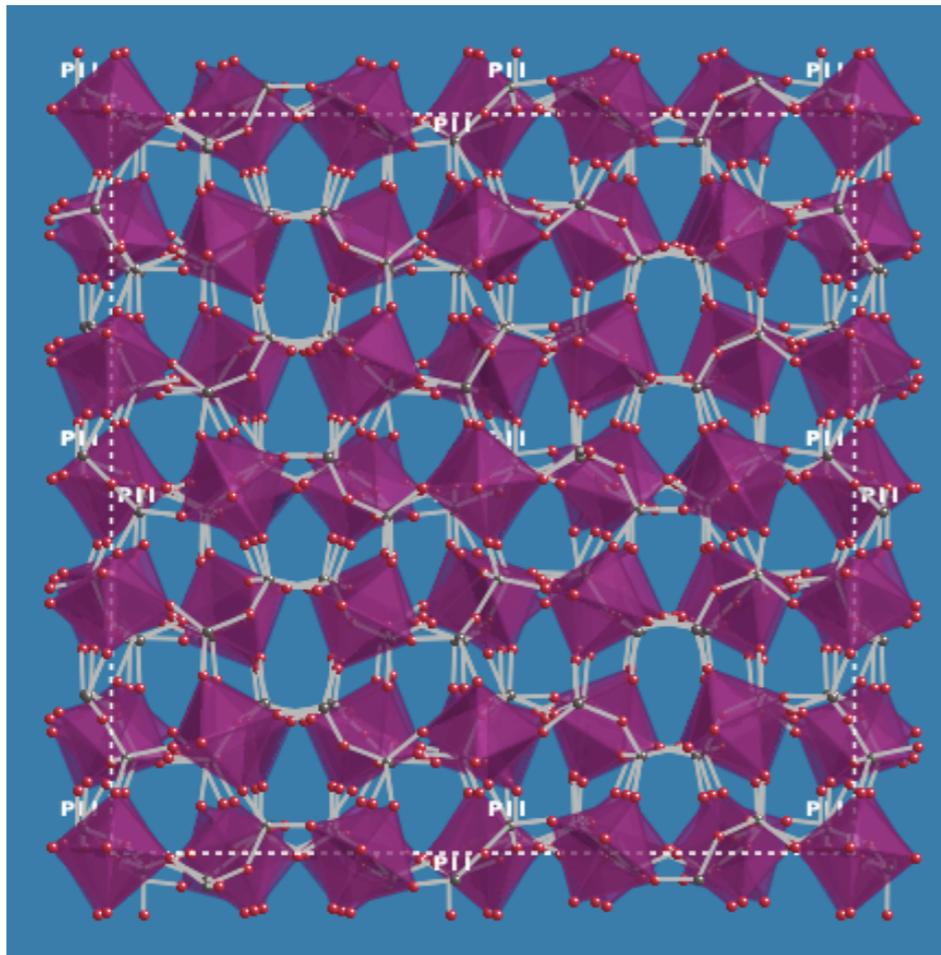

SAR-COSY and refocussed INADEQUATE result in similar sensitivity and contain similar information.

Structures of pyrophosphates

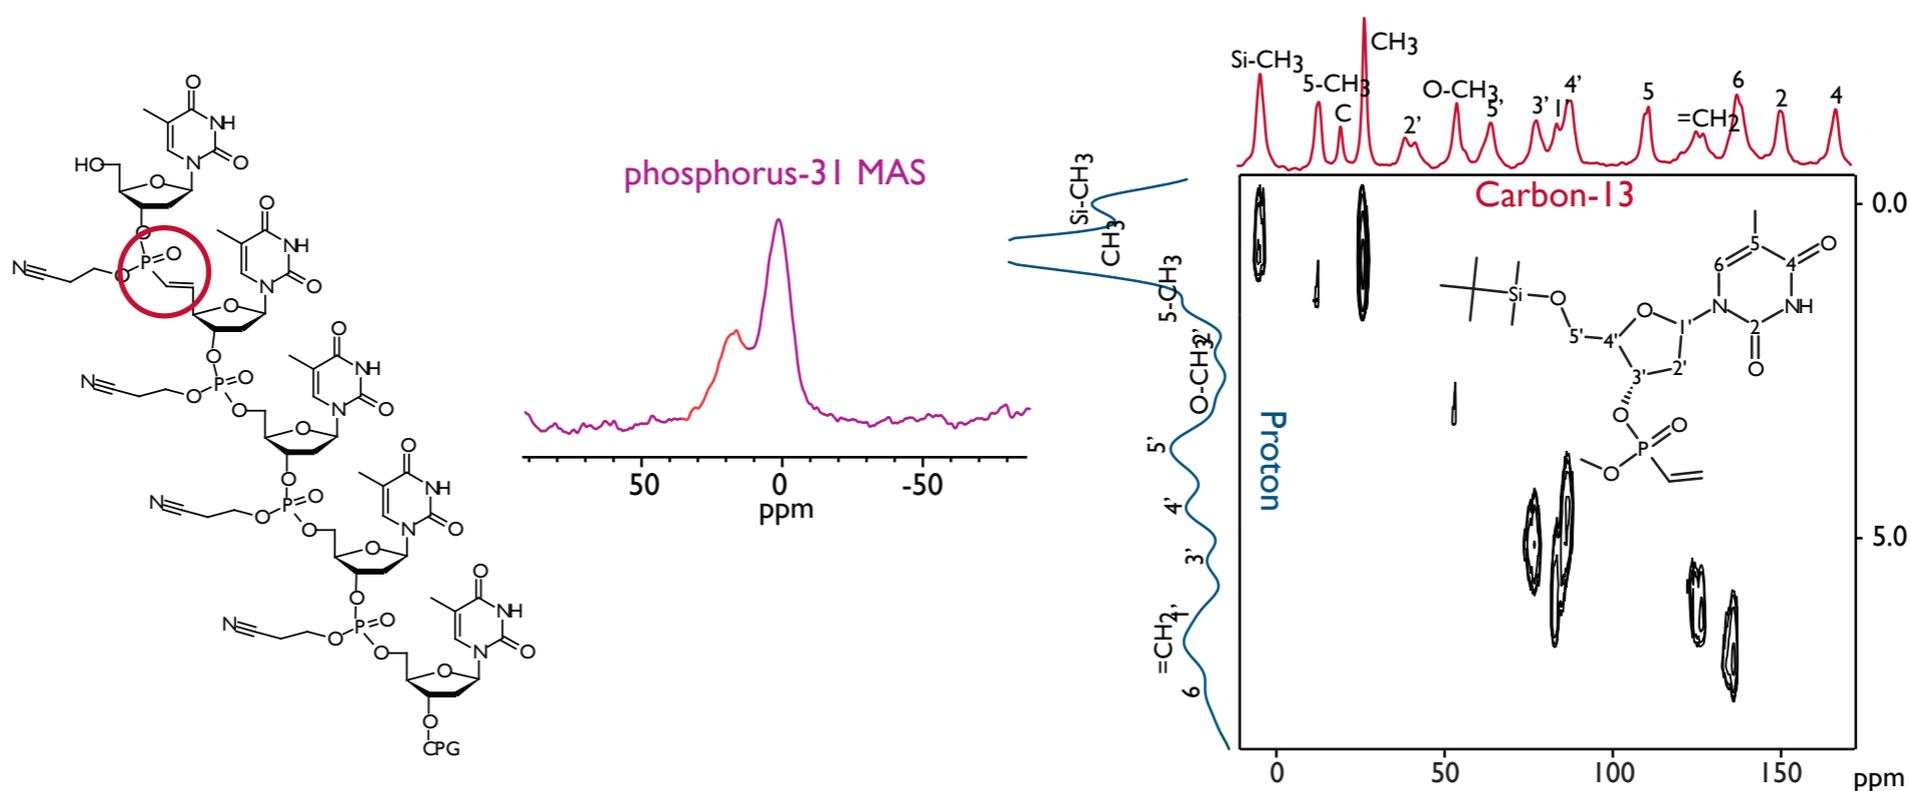

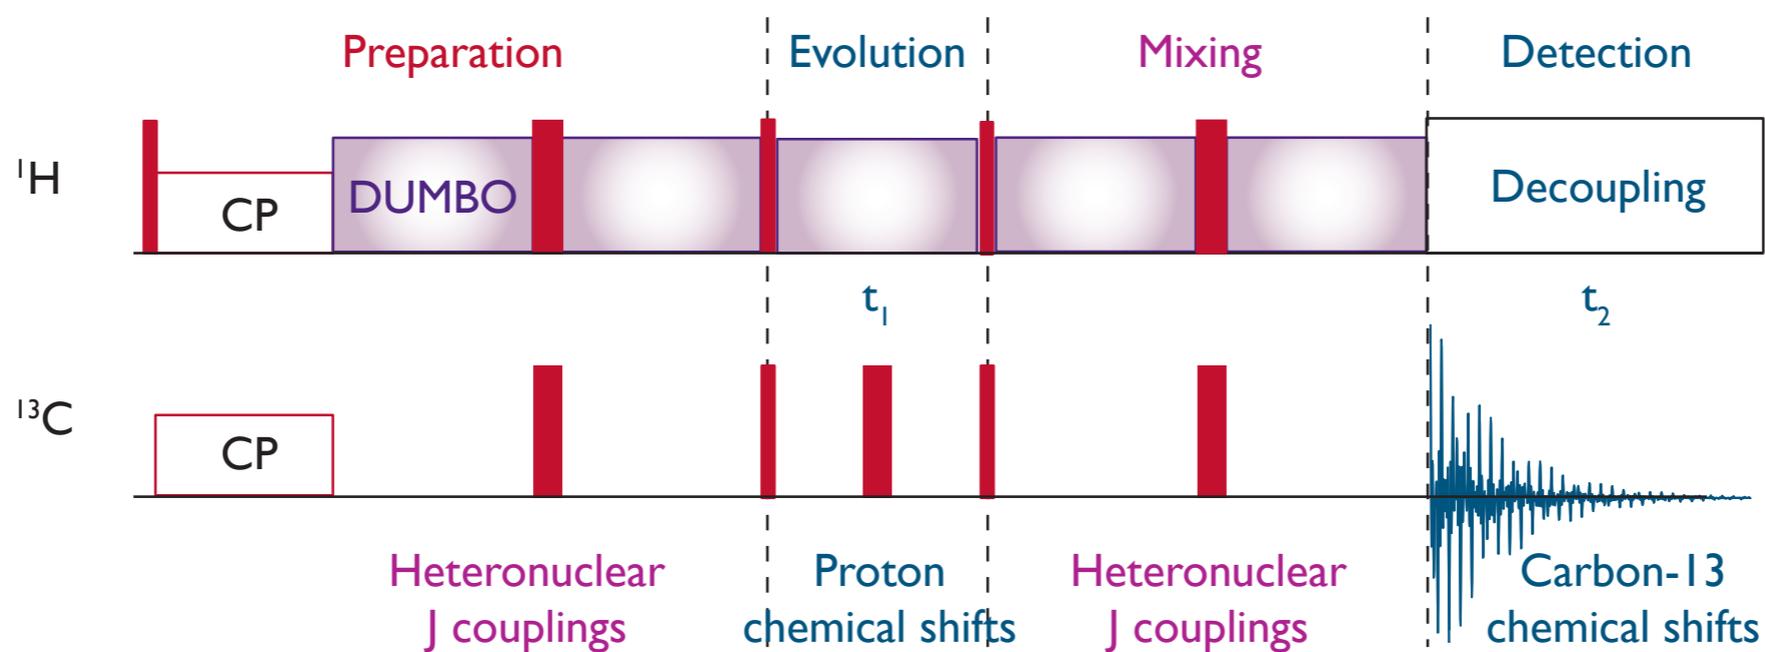

TiP₂O₇

- ★ This material has a cubic crystal structure with space group PA3-, $a = 23.534 \text{ \AA}$, $Z=108$
- ★ Scalar correlation experiments can distinguish 5 pairs of inequivalent ³¹P resonances bonded via a bridging oxygen atom and one equivalent pair.
- ★ This experiment can be used to distinguish between dynamic and static disorder in the P-O-P bond angle.

HMQC-J-MAS

With rapid MAS and efficient decoupling, many solid-state analogues of two-dimensional solution-state NMR experiments can be designed.

Summary

Two-dimensional **scalar and dipolar correlation** experiments show a high resolution spectrum in each dimension with cross peaks which map the correlations due to the mixing Hamiltonian.

Scalar correlations can be used for structural studies and for assignments, while dipolar correlations provide information about conformation.

Increasingly, solid-state NMR correlation experiments resemble their solution-state counterparts and make use of efficient decoupling, rapid MAS and anti-phase magnetization transfer under scalar couplings.
